Gene sequences specify the initial amino acid sequences of proteins as expressed by the ribosomes. However, complex enzymic reactions in the cell can greatly modify the chemical composition of mature proteins. There are numerous possible modifications such as trimming of the expressed sequence to remove signal peptides, cysteine oxidation to cystine and addition of functionalities such as phosphates, sulfates, oligosaccharides and lipids. Understanding these modifications may be fundamental to understanding the biological action of a protein. To some extent they may be predictable from the existence of a consensus sequence such as Asn-X-Thr or Asn-X-Ser for glycosylation of asparagine, but the extent of the modification may range from 0 to 100% of protein molecules. Also, because a process such as glycosylation is carried out by a complex cascade of enzymes, the glycoforms at a single site are frequently diverse in both structure and molecular mass. MS of a glycopeptide or glycoprotein will reveal the presence of the oligosaccharide by an increase in mass, but the potential heterogeneity may make it difficult to resolve the various glycoforms. Furthermore, mass alone will not distinguish the many isomeric forms of the individual monosaccharide units, their sequences or any branching patterns. The sugars can also be modified, e.g. by presence of phospholipids as in the glycosyl phosphatidylinositol-anchored proteins.

In order to determine the mass of the amino acid sequence of the protein alone the oligosaccharides can be removed chemically or with a glycosidase enzyme such as Endo-H or peptide *N*-glycosidase F (PNGase F). The released sugars can also be studied although their complete characterization may be more difficult than that of the peptide or protein. Tandem MS may identify the glycopeptides in a complex peptide mixture as CID gives low mass ions characteristic of the monosaccharide units, including m/z 163 (hexose), 204 (*N*-acetylhexose) and 292 (sialic acid). These masses are ideal for LC-MS-MS precursor ion scans to identify the glycopeptides and define their masses. Methods have been developed for the detection and analysis of *N*-linked and *O*-linked oligosaccharides and the more recently discovered but widespread *N*-acetyl glucosamine modification of serine (and threonine), which apparently plays a regulatory role similar to that of phosphorylation.

Figure 4 illustrates the complexity that can arise due to glycosylation. A 75-residue glycopeptide derived from the prion protein by digestion with endopeptidase Lys-C contained a single glycosylation site. The oligosaccharides attached to this site were highly heterogeneous, giving the complex ESI spectrum in **Figure 4a**, with the deconvoluted spectrum in **Figure 4b**. Treatment with PNGase F removed the sugars completely, leaving just

the amino acid chain. This gave a simplified spectrum from which a molecular mass of 8607.8 was determined. Subtraction of the mass of the deglycosylated peptide from those of the prominent glycopeptides gave the masses of the sugars, which could be related to partial structures for the glycoforms determined previously.

Modifications such as phosphorylation are chemically simpler and are more easily identified by MS, although the addition of 80 Da can be due to either a phosphate (HPO_3) or a sulfate (SO_3). Serine and threonine phosphates are acid sensitive and may not survive LC/MS, whereas tyrosine phosphates are generally more robust. Sulfate is also labile and may not be observed in positive ion MALDI but it usually can be identified by ESI or negative ion MALDI. The importance of phosphorylation in signalling and the control of cellular events has greatly increased interest in identification of protein phosphorylation sites. A valuable technique to locate phosphopeptides in a protein digest uses LC-ESI-MS-MS precursor ion scans of m/z 79 in the negative ion mode to identify all ions forming the characteristic fragment PO_3^- . The extent of phosphorylation may be much less than stoichiometric, so the same peptides may occur with and without phosphate. The identified phosphopeptides can be sequenced by MS-MS to identify the specific residues carrying the phosphate groups. A current challenge is to increase the sensitivity for detection and identification of such modifications in complex mixtures of proteins extracted from cells and tissues.

Disulfide bond analysis by MS is usually straightforward for proteins but is challenging for small cysteine-rich proteins and peptides such as the conotoxins which may contain as many as 6 cysteine residues within a peptide of only 20–30 amino acids. For a protein an effective strategy is to carry out chemical or enzymic digestion and peptide mapping on the native material after reduction with dithiothreitol and alkylation of the cysteines using a reagent such as iodoacetic acid. The addition of a carboxymethyl group to a cysteine increases the mass by 58 Da, so cysteine-containing peptides are readily detected by comparison with a digest of the unmodified protein. A protein digest with the disulfide bonds intact will result in some peptides linked by the disulfides. If these are not identifiable on the basis of mass alone, they may be separated by HPLC, reduced and then analysed as two separate peptides.

Noncovalent Interactions and Analysis of Higher Order Structure

Peptides and proteins do not carry out their biological functions in isolation. Their active forms may be associated with metal ions, small molecules, macromolecules including proteins and DNA, and they may form complex multiprotein assemblies. Biological processes occur

Figure 4 (a) ESI-MS spectrum of a 75-residue glycopeptide from the prion protein showing multiple peaks due to oligosaccharide heterogeneity. (b) Deconvolution of the spectrum in (a) showing molecular masses rather than m/z .

in aqueous solution in the presence of salts and other ions, whereas MS is used to probe substances isolated *in vacuo*, conditions that could be incompatible. Despite this, the use of MS to study these interactions is growing rapidly. MALDI, which ionizes directly from the solid phase, does not lend itself to studies that mirror solution conditions, but ESI, which abstracts ions directly from solution by rapid evaporation of nebulized droplets, can monitor noncovalent associations very successfully.

The most successful studies have been on systems involving electrostatic rather than hydrophobic interactions. The metal-binding properties of a peptide (or protein) can be monitored directly from aqueous solution of perhaps 10 μ M peptide containing the metal cation salt at various concentrations. The pH is controlled by the use of a weak buffer such as 1–10 mM ammonium acetate. An equilibrium in solution between free peptide and the complex can be preserved during the rapid

drying of the microdroplets, occurring within 0.5 ms. Low micromolar dissociation constants derived from the peak intensities are similar to those obtained by conventional methods. Although removal of the dielectric shielding effect of water might encourage random binding of cations to negative amino acids, strong specific binding can be clearly distinguished from weak nonspecific effects. Peptides homologous to some ATP-ases containing His-X-His or His-X-X-His bound either Cu^{2+} or Ni^{2+} but not Zn^{2+} , whereas analogous peptides with a single histidine bound only Cu^{2+} . By contrast a peptide corresponding to a region of the Alzheimer's precursor protein having the motif His-X-His-X-His was seen to bind all three divalent cations.

Figure 5 shows partial mass spectra at two time points for a metal ion transfer reaction between metallothionein coordinated with 7 zinc ions and carbonic anhydrase. The conversion of the apo form to the holo form was

Figure 5 A metal transfer reaction between metallothionein- Zn_7 and carbonic anhydrase at pH 7.5 monitored by ESI-MS showing the major peaks for carbonic anhydrase, (a) after 3.5 min, and (b) after 43.5 min. Reproduced with permission of Cambridge University Press from Zaia Z, Fabris D, Wei D, Karpel RL, and Fenselau C (1998) Monitoring metal ion flux in reactions of metallothionein and drug-modified metallothionein by electrospray mass spectrometry. *Protein Science* 7: 2398–2404.

monitored over a wide pH range for up to 120 min. It was also seen that zinc ion uptake was associated with addition of a hydroxyl radical or water molecule. Such an experiment gives direct information about the stoichiometry of reaction intermediates and complexes and can yield kinetic and thermodynamic data.

Complexes between the trp repressor (TrpR) and its specific operator DNA were monitored in a competition experiment. When TrpR was mixed with an equimolar mixture of DNA containing two consensus sequences separated by 2, 4 or 6 base pairs, 1:1 protein:DNA complexes formed only with DNA having the 4-bp spacer. The dimerization of the AIDS protease has also been demonstrated by ESI but hydrophobic interactions such as this are stabilized by the dielectric of the solvent and by the presence of salts. This stabilization is lost on transfer to the gas phase, necessitating very mild conditions for the nebulization, evaporation and transfer of such delicate complexes into the vacuum system.

ESI-MS studies at neutral pH of proteins in their native state usually results in the attachment of far fewer protons compared with ionization from acidified solution.

Consequently m/z values are frequently 5000 or more and may range up to 10 000. Such species are beyond the normal working range of many mass spectrometers including most quadrupoles and ion traps, but they can be studied with TOF or high field magnetic instruments.

Hydrogen–Deuterium Exchange

MS is obviously well suited to establishing the primary amino acid sequence and posttranslational modifications of peptides and proteins and it also has a role in determining the quaternary structure, i.e. the non-covalent association of subunits in multiprotein assemblies. What is less apparent is that hydrogen–deuterium exchange allows secondary and tertiary structure to be probed. Other techniques commonly used for such biophysical studies include optical spectroscopy, fluorescence, circular dichroism, light scattering, NMR and X-ray crystallography. Only the last two of these can give a detailed 3D molecular structure; the others give integrated views that obscure individual features. MS requires much less material than any other method and can follow the dynamics of rapid protein folding and unfolding.

The amide hydrogens along the protein backbone and in some sidechain positions are labile and undergo rapid exchange with solvent protons unless they are involved in hydrogen bonding. Secondary structural elements such as helices and sheets are maintained by hydrogen bonds, as are many aspects of tertiary structure. The rate of exchange of such protected hydrogens is usually reduced dramatically. Usually a peptide or protein can be deuterated fully by lengthy exchange in D_2O , each deuteron increasing the mass by 1 Da, so that the total increase gives a measure of the number of exchangeable hydrogen atoms. The accessibility of these atoms is assessed by measuring the rate of back exchange with H_2O . Above pH 3 the rate of hydrogen exchange for freely accessible hydrogens is proportional to $[OH^-]$, i.e. it is approximately 10 000 times faster at physiological pH than at pH 3. After carrying out the exchange reaction at pH 7.4, the reaction can be effectively frozen by taking aliquots at different times and rapidly dropping both the pH and the temperature. The aliquots can then be analysed by ESI-MS to determine the degree of exchange. Alternatively the exchange process occurs in a flowing stream in which the reagents mix for a controlled period of time before being quenched by mixing with an acidified solution and then injected directly into the ESI source.

Peptides can be sequenced by MS-MS to determine the precise location of the deuterons. However, it is usually essential to employ intact proteins rather than shorter peptides to address questions concerning secondary and tertiary structure, but the location of the deuterons in a protein requires digestion to peptides after exchange. Fortunately the nonspecific protease pepsin is

Figure 6 Deuterium incorporation into specific segments of cytochrome C as a function of temperature, showing thermal melting at 58–64 °C of α -helical regions. most active at the low pH values at which further exchange is minimized. Samples of the protein that have been subjected to back exchange can be digested quickly using a high enzyme:substrate ratio, then separated and analysed rapidly by LC-MS using fast flow rates through chilled, highly porous HPLC columns. Deuterium incorporation into specific segments of cytochrome C as a function of temperature is illustrated in **Figure 6**. This shows strong evidence for thermal denaturation with a sharp transition at 58–64 °C that affects only the most structured regions known to be involved in α -helices.

Conclusions

MS is a critically important method for the identification and characterization of peptides and proteins. This role will continue to grow as proteomic studies spur the demand for

high throughput protein analysis and characterization. Many mass spectrometric techniques lend themselves to rapid analysis using automation and robotics, particularly MALDI for which it is already easy to deposit hundreds or even thousands of samples on a single target plate and to programme the mass spectrometer to collect a spectrum for each one. One serious factor limiting further exploitation is the availability of suitable computerized data systems to analyse and summarize the enormous quantities of data such automation can yield. However, it is likely that the concerted efforts of the academic community, mass spectrometer manufacturers and major users, such as multinational pharmaceutical companies, will successfully solve such problems quite rapidly.

ΔG^0	free energy change under standard conditions
ΔG_{ATP}	free energy of hydrolysis of ATP

Introduction

Studies of isolated, perfused organs have been invaluable in furthering our knowledge of metabolism and function. This experimental system allows the direct observation of the effects of an intervention on an organ in the absence of neurohumoral control mechanisms. Experimental conditions are simpler to control, and to modify, in isolated organs than in the whole animal. Isolated organs also maintain important intercellular interactions that do not take place in isolated cells, subcellular organelles or cellular homogenates. Nuclear magnetic resonance (NMR) spectroscopy of these organs has greatly increased the versatility and power of such studies. NMR spectroscopy allows data to be collected nondestructively throughout the experimental protocol in discrete time segments. The types of data that can be acquired include information on energy status, ion homeostasis, substrate utilization and enzyme activities (Table 1). Most studies have been performed using isolated hearts. Liver, kidney and skeletal muscle have been used to a lesser extent. In addition to furthering knowledge of biochemistry and physiology, such studies have provided a basis for the development of *in vivo* NMR spectroscopy as a tool for assessing normal and pathophysiological function in humans. This article will describe the uses of ^{31}P , ^{23}Na , ^{13}C , ^1H , ^{19}F , ^{87}Rb and ^7Li NMR spectroscopy in cardiac physiology and pathophysiology. The application of these techniques to studies of isolated liver and kidney will also briefly be described.

Studies of Isolated Hearts

NMR spectroscopy has been performed on hearts isolated from a wide variety of species including dog, pig, sheep, rabbit, turkey, ferret, guinea-pig, rat and mouse. Hearts from the larger animals have been studied in horizontal-bore magnets with a clear bore of 20–30 cm and operating at field strengths of 4.7–7.0 T. Rodent hearts have generally been studied in vertical-bore magnets with a clear bore of approximately 8 cm and operating at field strengths of 4.7, 8.7, 9.4 and 11.75 T. In most studies, perfusion is performed with a modified Krebs–Henseleit buffer with the approximate composition (mM) NaCl 118, KCl 4.7, MgSO_4 1.2, NaHCO_3 25 and with CaCl_2 varied between 1.2 and 2.5 mM depending upon the species. Ethylenediaminetetraacetic acid (EDTA) is often added at a concentration of 0.5 mM to chelate heavy-metal contaminants. For studies involving ^{31}P spectroscopy, phosphate is normally omitted from the perfusate to allow identification and quantification of the intracellular inorganic phosphate (P_i) peak. For other studies, perfusate may be supplemented with phosphate at a final concentration of 1.2 mM. The perfusate is aerated with 95% O_2 /5% CO_2 to achieve a pH of 7.4, a $p_{\text{O}_2} > 600$ mmHg and a p_{CO_2} of 35–45 mmHg. Glucose (11 mM) is often supplied as the sole substrate source, although in many situations a mixture of glucose and pyruvate (or other substrates) is used. For studies of hearts from the larger species, the perfusate is supplemented with serum albumin to minimize the oedema

that results from perfusion with crystalloid solutions. The use of crystalloid perfusate results in coronary flows ~ 3 times those observed under conditions where whole blood or buffers supplemented with washed red cells are used.

Hearts can be perfused in two modes: the working heart preparation and the isovolumic (or Langendorff) preparation. Both methods allow assessment of cardiac mechanical function throughout the experimental protocol. For both preparations, the ascending aorta is cannulated and retrograde perfusion of the aorta is initiated. In Langendorff preparations, perfusion is continued in this manner and the coronary arteries are continuously perfused throughout the protocol. Perfusion is performed under conditions of constant pressure (60–80 mmHg) or of constant flow by means of a pump. A compliant water-filled balloon is inserted into the left ventricle and connected to a pressure transducer in order to measure left ventricular pressure. The balloon is inflated to achieve a relevant end-diastolic pressure (generally in the region of 10 mmHg). In the working heart preparation, following stabilization in the Langendorff mode, the left atrium is cannulated and perfusion is continued through this chamber. The perfusate enters the left ventricle and is ejected into the aorta. Perfusion of the coronaries occurs during diastole when the aortic valve closes. Cardiac function is assessed on the basis of cardiac output (measured with flow probes) and aortic pressures. Owing to the physical constraints imposed by working within a magnet, most MR spectroscopy studies are performed using the Langendorff preparation. Temperature regulation is achieved using water-jacketed perfusion lines, by immersing the heart in the perfusion buffer and by means of a flow of warm air within the bore of the magnet.

Hearts isolated from rodents can be contained within commercially available NMR tubes (20–30 mm) and make use of commercially available broadband or nuclei-specific NMR probes. Studies on hearts from larger mammals generally require an organ bath that incorporates a custom-built NMR coil within its structure or a surface coil attached to the left ventricular wall.

³¹P NMR Spectroscopy

³¹P NMR spectroscopy is widely used for studies of isolated hearts. Using the endogenous ³¹P signal arising from the tissue, it is possible to obtain information about the energy status of the heart and also to determine the intracellular pH (from the chemical shift of P_i). Assessment of extracellular pH is also possible using phosphonates that are confined to the extracellular space (e.g. phenylphosphonic acid or methylphosphonic acid). The heart metabolizes substrates (fatty acids, ketones, lactate, glucose, etc.), with the resultant energy being stored in the high-energy

phosphate compound adenosine triphosphate (ATP). Most of this ATP is formed by mitochondrial oxidative phosphorylation. The phosphocreatine shuttle is responsible for transferring the energy from this mitochondrial ATP to sites of energy expenditure at the myofibrils and sarcolemma. **Figure 1** shows a typical ³¹P spectrum obtained from an isolated guinea-pig heart. The phenylphosphonic acid, which acts as an external standard, is contained within a capillary tube placed alongside the heart and contained entirely within the coil of the NMR probe. ³¹P NMR can detect phosphorus-containing compounds that are present in the fluid phase at concentrations of 0.6 mM or greater. The compounds visible by this technique are inorganic phosphate (P_i), phosphomonoesters (in this case sugar phosphates), phosphocreatine (PCr) and adenosine triphosphate (ATP). Adenosine diphosphate (ADP) is not visible because most of this nucleotide is protein bound within the cardiomyocytes.

Spectra are routinely collected with a repetition time of approximately 2 s, permitting the acquisition of data with adequate signal-to-noise in 2–5 min. This leads to 10–20% saturation of the PCr signal ($T_1 \approx 3$ s in rat heart at 8.7 T). The free induction decays are normally subjected to Fourier transformation following exponential multiplication using an appropriate line broadening (5–20 Hz). In many situations, alterations in the high-energy phosphate content of the heart over the course of an experiment are expressed as changes relative to the starting level. Absolute quantification of metabolite levels can be achieved by the use of an appropriate external reference (e.g. phenylphosphonic acid in **Figure 1**) and correction for the partial saturation of the PCr signal. ATP contents are determined from the integral of the β ATP peak; the α and γ ATP peaks overlap with resonances from other molecular species. The PCr and β ATP phosphates are 100% NMR-visible under aerobic conditions. The free ADP concentration can be calculated from the creatine kinase equilibrium equation,

$$K_{eq} = \frac{[Cr][ATP]}{[PCr][ADP][H^+]} \quad [1]$$

where total creatine is normally determined biochemically and free [Cr] is determined from the difference between total [Cr] and [PCr]. Literature values for K_{eq} are $\sim 10^9$. The free energy of hydrolysis of ATP may be calculated from

$$\Delta G_{ATP} = \Delta G_0 + RT \ln \frac{[ADP][P_i]}{[ATP]} \quad [2]$$

where ΔG^0 is taken to be $-30.5 \text{ kJ mol}^{-1}$. It is often suggested that ΔG_{ATP} more accurately reflects the energetic capabilities of tissue than does a determination of the levels of high-energy phosphates.

Figure 1 ^{31}P NMR spectrum of a guinea-pig heart perfused with Krebs–Henseleit solution. The spectrum was acquired at 8.7 T using a broadband probe tuned to 145.8 MHz. Peak assignments are 1, phenylphosphonic acid (external reference); 2, phosphomonoesters; 3, inorganic phosphate (P_i); 4, phosphocreatine (PCr); 5, γ -phosphorus of adenosine triphosphate (ATP); 6, α -phosphorus of ATP; 7, β -phosphorus of ATP. The spectrum was acquired in 2.5 min by summing 72 free induction decays (FIDs) with a 35 μs pulse and a repetition time of 2 s. Prior to Fourier transformation, the FID was subjected to exponential multiplication with a 20 Hz line broadening factor.

^{31}P NMR can also be used to determine intracellular pH from the pH-dependent chemical shift of P_i using the following formula based on the Henderson–Hasselbach equation:

$$\text{pH} = \text{p}K + \log[(\delta - 3.27)/(5.69 - \delta)] \quad [3]$$

where $\text{p}K = \text{p}K_2$ of inorganic phosphate (6.75). This technique yields an intracellular pH of 7.10–7.20 when the heart is perfused with buffer at pH 7.4.

^{31}P NMR spectroscopy has been applied to questions relating both to normal and to pathophysiological conditions. It has been used in the normal heart to investigate the regulation of cardiac energy supply in response to increased demand. This study showed that there is no simple equilibrium between the phosphorylation potential and the mitochondrial redox state and that other factors are involved in coordinating energy supply and demand.

^{31}P NMR spectroscopy has also been used to study the mechanisms responsible for myocardial ischaemia–reperfusion injury. During ischaemia, blood (or perfusate) flow is restricted or totally occluded, resulting in an insufficient supply of oxygen to support oxidative metabolism. Anaerobic metabolism, in the form of glycolysis, is

stimulated but is not adequate to maintain the energy balance. This leads to a depletion of high-energy phosphates. In addition, intracellular acidosis develops as a result of ATP hydrolysis and the accumulation of acidic end products of glycolytic metabolism. ^{31}P NMR spectroscopy can follow the time course of changes in intracellular pH and high-energy phosphates during ischaemia and reperfusion (Figure 2). The effects of drug interventions on these profiles can provide insights into the mechanisms responsible for any observed cardio-protection conferred by the drug. Such studies also provide essential information on the roles of high-energy phosphate depletion and intracellular acidosis in ischaemia–reperfusion injury.

^{23}Na NMR Spectroscopy

Ionic concentration gradients exist across cell membranes and are responsible for maintaining the resting membrane potential. Intracellular and extracellular Na^+ are approximately 10 mM and 140 mM, respectively. The converse is true for K^+ , with an intracellular concentration of 130–140 mM and an extracellular concentration of 4–5 mM. Sodium enters the cells of excitable tissue during the up stroke of the action potential and potassium leaves the cell during the repolarization phase.

Figure 2 Time course of changes in intracellular pH (◆), ATP (□) and PCr (●) in a rat heart subjected to 25 min of total global ischaemia followed by 30 min of reperfusion. pH was determined from the chemical shift of P_i . Changes in ATP and PCr are expressed as percentage change from the basal levels measured prior to ischaemia. Total global ischaemia was achieved by stopping all flow of perfusate to the heart.

The gradients are maintained by the operation of a Na^+K^+ ATPase (the sodium pump) that exchanges intracellular Na^+ for extracellular K^+ . In the heart, these ionic gradients can be disrupted by factors that prevent full activity of the sodium pump such as ischaemia or drugs (e.g. the cardiac glycosides related to digitalis). The ability to measure intracellular Na^+ levels in the intact heart makes ^{23}Na NMR spectroscopy a very powerful technique for assessing the role of altered Na^+ homeostasis in disease states.

Intracellular water represents about half the total water of the intact heart, the exact proportion being dependent on the species and perfusion conditions. This fact and the low intracellular concentration mean that, of the total Na^+ signal from the heart, less than 3% originates from the intracellular Na^+ . Several studies have used double- or triple-quantum filtering techniques to discriminate this small intracellular Na^+ signal from the dominant extracellular Na^+ signal. Most studies, however, make use of non-cell-permeant paramagnetic reagents to 'shift' the extracellular peak and allow quantification of the intracellular Na^+ signal. These shift reagents are anionic chelates of lanthanide ions that do not cross membranes and thus are excluded from the intracellular space. The original agent used for this purpose, dysprosium bis (triphosphate), $Dy(PPP)_2^{7-}$ possesses the largest paramagnetic shift of any such complex for Na^+ or K^+ . However, this reagent is quite sensitive to Ca^{2+} and Mg^{2+} and the shifts produced are greatly reduced by the presence of these ions. This fact precludes the use of $Dy(PPP)_2^{7-}$ in the intact heart, which requires both Ca^{2+}

and Mg^{2+} for full functional integrity. The triethylenetetraminehexaacetic acid chelate of dysprosium, $Dy(TTHA)^{3-}$, produces smaller shifts but is much less sensitive to the effects of Ca^{2+} and Mg^{2+} . For studies in intact hearts that use $Dy(TTHA)^{3-}$, perfusates containing the shift reagent must be supplemented with Ca^{2+} to offset the Ca^{2+} -chelating properties of the shift reagent. This is well tolerated by the heart and results in adequate mechanical function. $Dy(TTHA)^{3-}$ at 5 mM not only causes a significant shift in the extracellular peak but also results in considerable line broadening, which still makes it somewhat difficult to fully resolve the small intracellular peak without specific processing strategies to maximize the resolution (**Figure 3**). Increasing the concentration of the shift reagent will cause a larger shift; however, the benefit is offset by an increase in line broadening.

The most recent shift reagent to be introduced is the tetraazacyclododecane-1,4,7,10-tetrakis(methylenephosphonate) chelate of thulium, $Tm(DOTP)^{5-}$ (**Figure 4**). This shift reagent also chelates Ca^{2+} and the perfusate must be supplemented with Ca^{2+} to maintain adequate mechanical function. At 4–5 mM, $Tm(DOTP)^{5-}$ causes a significant shift in the extracellular Na^+ signal with very little line broadening. This latter property of the shift reagent makes it possible to perform interleaved ^{31}P and ^{23}Na NMR spectroscopy (in conjunction with a switchable NMR probe) in the presence of $Tm(DOTP)^{5-}$. Such studies are not possible in the presence of $Dy(TTHA)^{3-}$ owing to the excessive line broadening effects.

This strategy has been successfully applied to studies on isolated rat hearts to determine the involvement of

Figure 3 ^{23}Na NMR spectra of a rat heart in the presence of 5 mM Dy(TTHA) $^{3-}$. Spectra were acquired at 8.7 T using a broadband probe tuned to 95.25 MHz. The lower trace is a spectrum acquired during normal perfusion. The addition of shift reagent to the perfusate has shifted the large extracellular Na^+ peak 2 ppm downfield and has also caused a 0.2 ppm shift in the smaller intracellular Na^+ peak. The upper trace is a spectrum acquired following 25 min of total global ischaemia. The intracellular Na^+ peak has grown substantially, reflecting the intracellular Na^+ accumulation that occurs during ischaemia. Resolution of the peaks was enhanced using Gaussian multiplication with line broadening of 25 Hz and a GB parameter of 0.15.

Figure 4 Tm(DOTP) $^{5-}$.

the $\text{Na}^+\text{--H}^+$ exchanger in ischaemia–reperfusion. This sarcolemmal protein exchanges one Na^+ for one H^+ . It is thought that this exchanger may contribute to myocardial ischaemia–reperfusion injury. During ischaemia, intracellular

acidosis develops and this activates the $\text{Na}^+\text{--H}^+$ exchanger. This leads to an increase in intracellular Na^+ as intracellular H^+ is exchanged for extracellular Na^+ . The increased intracellular Na^+ may activate the $\text{Na}^+\text{--Ca}^{2+}$ exchanger, with intracellular Na^+ exchanging with extracellular Ca^{2+} . The end result is an increase in intracellular Ca^{2+} , which may be a major factor in the deleterious effects of ischaemia–reperfusion injury. ^{31}P and ^{23}Na NMR experiments performed in the presence of Tm(DOTP) $^{5-}$ provided data on intracellular pH and the Na^+ content. Inclusion of a relatively specific inhibitor of the $\text{Na}^+\text{--H}^+$ exchanger (ethyl isopropyl amiloride) in the perfusate partially attenuated the changes in pH and Na^+ and significantly decreased mechanical dysfunction following ischaemia–reperfusion. This provided good evidence for the involvement of the $\text{Na}^+\text{--H}^+$ exchanger in ischaemia–reperfusion injury and confirmed the presumed mechanism of action of the drug. In most studies, only relative changes in Na^+ levels are reported rather than intracellular concentrations. This is in large part due to the need to make assumptions regarding the visibility of the Na^+ NMR signal under various experimental conditions.

^{13}C NMR Spectroscopy

Most studies on isolated hearts use glucose as the sole energy source. Normally, the heart would be exposed to a variety of substrates including glucose, pyruvate, lactate, acetoacetate and a mixture of fatty acids. ^{13}C NMR spectroscopy has been used to demonstrate that fatty acids and acetoacetate are the preferred substrates for the heart under normal physiological conditions. It is also important to determine how substrate selection and the efficiency with which the heart metabolizes these substrates are altered under pathological conditions. The citric acid cycle is the central pathway for energy production in the heart and it is critical to determine how the flux of metabolites through this pathway is altered in diabetes and cardiomyopathy and during reperfusion of the ischaemic myocardium. Citric acid cycle flux has been determined indirectly by measuring the enrichment of ^{13}C into glutamate from α -ketoglutarate by the action of aspartate aminotransferase. For these studies, hearts are provided with substrate, or substrate mixtures, highly enriched with ^{13}C at specific carbon atoms (e.g. [1- ^{13}C]glucose, [1, 2- ^{13}C]acetate, [3- ^{13}C]lactate, etc.). The contribution of selected substrates to overall citric acid cycle activity may then be determined by isotopomer and multiplet analyses of ^{13}C enrichment in glutamate. Such studies have been performed under steady-state and non-steady-state conditions. Analyses are most usually performed by high-resolution spectroscopy on trichloroacetic acid extracts of hearts perfused with ^{13}C -enriched substrates, although useful data

can be obtained by performing spectroscopy on intact beating hearts. The Krebs cycle flux has been measured in real time in perfused rat hearts using hyperpolarized 2- ^{13}C -pyruvate and reported for the first time in 2009. This technique, explained in other articles in this encyclopedia (check the “See also” list at the end) enables much greater signal-noise ratios in NMR spectra. The hyperpolarized pyruvate was infused into isolated perfused hearts in both healthy and post-ischemic metabolic states, and the enzymatic conversion of pyruvate to lactate, acetylcarnitine, citrate, and glutamate was studied with 1s temporal resolution. The appearance of ^{13}C -labeled glutamate was delayed compared with that of other metabolites, indicating that Krebs cycle flux can be measured directly. The production of ^{13}C -labeled citrate and glutamate was decreased post-ischemia, as opposed to lactate, which was significantly elevated.

^1H NMR Spectroscopy

The abundance of ^1H in water forms the basis for most magnetic resonance imaging. However, ^1H NMR spectroscopy has not found such universal applicability to studies of isolated hearts. This technique has been used to quantify the total content of creatine, which may provide a useful index of tissue viability. ^1H NMR spectroscopy has also been used to determine lactate levels during ischaemia and following interventions designed to modulate metabolism. The lactate methyl group and lipid methylene groups resonate at 1.3 ppm. These resonances can be differentiated and quantified using spin-echo spectral editing techniques.

^{19}F NMR Spectroscopy

The most important use of ^{19}F NMR spectroscopy in studies of isolated hearts is to measure intracellular Ca^{2+} levels. This is based on the use of fluorinated derivatives of calcium chelators. The extracellular Ca^{2+} concentration is ~ 1.2 mM. The intracellular Ca^{2+} concentration at diastole is less than 100 nM. This increases to several hundred nM during cardiac excitation. This elevated Ca^{2+} (or calcium transient) is responsible for contractile activity at each heartbeat. Efficient relaxation at each beat depends upon the intracellular Ca^{2+} being restored to diastolic levels. Most of the cytosolic Ca^{2+} enters the cell through voltage-regulated Ca^{2+} channels during the plateau phase of the action potential or is released from the intracellular organelle, the sarcoplasmic reticulum. Diastolic Ca^{2+} levels are restored by active pumping of the Ca^{2+} back into the sarcoplasmic reticulum and by activation of the sarcolemmal $\text{Na}^+/\text{Ca}^{2+}$ exchanger, exchanging intracellular Ca^{2+} for extracellular Na^+ . Thus, the level of Ca^{2+} within the cardiac cell is tightly controlled under normal physiological conditions. If the intracellular level of Ca^{2+} rises

Figure 5 5F-BAPTA.

significantly above normal physiological limits, consequences may be deleterious as a result of activation of Ca^{2+} -dependent proteases and phospholipases and also due to mitochondrial damage.

Intracellular Ca^{2+} has been measured by ^{19}F NMR spectroscopy of intact hearts loaded with the 5,5'-difluoro derivative of 1,2-bis(*o*-aminophenoxy)ethane N,N,N',N' -tetraacetic acid (5F-BAPTA) (**Figure 5**). 5F-BAPTA is loaded into the heart as the cell-permeant acetoxy-methyl (AM) ester. Esterases within the cardiomyocyte hydrolyse the AM ester to the free acid, which, being charged and therefore unable to cross the cell membrane, is trapped within the cell. The calcium-bound and calcium-free 5F-BAPTA species undergo slow exchange resulting in two NMR-visible peaks. The intracellular Ca^{2+} concentration is calculated using the relation

$$[\text{Ca}^{2+}] = K_d \frac{[\text{B}]}{[\text{F}]} \quad [4]$$

where K_d is the dissociation constant of Ca^{2+} -5F-BAPTA (literature values of 537, 500, 635 and 285 nM), $[\text{B}]$ is the area under the Ca^{2+} -5F-BAPTA peak and $[\text{F}]$ is the area under the 5F-BAPTA peak.

A K_d of approximately 500 nM makes 5F-BAPTA an ideal probe for measuring intracellular Ca^{2+} in the physiologically relevant range (100 nM to 1 μM). Unfortunately, a K_d of 500 nM also causes 5F-BAPTA to provide excellent buffering to intracellular Ca^{2+} levels. This causes a decrease in mechanical function of the heart. When 5F-BAPTA is present within cardiomyocytes at sufficiently high concentration (300 μM) to provide adequate signal to noise in the ^{19}F NMR spectrum ($> 10:1$), developed pressure is reduced by 75–80%. This results from an increase in diastolic pressure and a decrease in systolic pressure. Thus, although studies using 5F-BAPTA can provide valuable information regarding changes in intracellular Ca^{2+} , it must always be borne in mind that these results were acquired under conditions of severely compromised cardiac function.

A BAPTA derivative with a higher K_d overcomes the problem of buffering of intracellular Ca^{2+} . The analogue

Figure 6 TF-BAPTA.

1,2-bis(2-amino-5,6-difluorophenoxy)ethane- N,N',N' -tetraacetic acid (TF-BAPTA) (**Figure 6**) has a K_d of 65 μM . Loading of intact hearts with this derivative causes <10% decrease in mechanical function. This high K_d causes TF-BAPTA to be a less accurate probe for measuring basal Ca^{2+} levels but does make it more suitable for measuring intracellular Ca^{2+} under pathophysiological conditions (e.g. ischaemia) where $[\text{Ca}^{2+}]$ may rise above 2 mM. The Ca^{2+} -bound and Ca^{2+} -free TF-BAPTA species are in intermediate-fast exchange. This leads to a single resonance with its chemical shift position being dependent upon the extent of Ca^{2+} binding (analogous to the pH-dependent shift in the P_i peak). Binding of Ca^{2+} to TF-BAPTA does not alter the chemical shift of the fluorine in the 6 position of TF-BAPTA. The fluorine in the 5 position shifts downfield upon binding of Ca^{2+} . The chemical shift difference between the 5 and 6 fluorines is used to determine intracellular $[\text{Ca}^{2+}]$ (with corrections for the effects of pH and $[\text{Mg}^{2+}]$). TF-BAPTA accumulates in the sarcoplasmic reticulum (SR) and this property has been used to determine $[\text{Ca}^{2+}]$ in this subcellular organelle in intact rabbit hearts. A 5-F resonance at 5 ppm (with the 6-F resonance set at 0 ppm) corresponds to a time-averaged basal cytosolic $[\text{Ca}^{2+}]$ of 600 nM. A second 5-F resonance at 14 ppm corresponds to a SR $[\text{Ca}^{2+}]$ of 1.5 mM. This technique may prove to be invaluable in assessing the role of alterations in SR Ca^{2+} handling in various pathological conditions.

^{87}Rb and ^7Li NMR Spectroscopy

^{23}Na spectroscopy is useful for measuring steady-state levels of intracellular sodium but is not suitable for measuring fluxes of this cation. The contribution of various ion channels, exchangers and pumps to the total movement of ions across the sarcolemmal membrane can be assessed by measuring ion fluxes in the presence and absence of selective inhibitors of these membrane proteins. It is possible to acquire this type of information

using electrophysiological techniques. These data would be complemented by the use of techniques that can measure ion fluxes in the intact heart. ^{87}Rb and ^7Li , congeners of K^+ and Na^+ , respectively, have been used to assess fluxes of K^+ and Na^+ in intact hearts and vascular tissue. For ^{87}Rb spectroscopy, 20% of the perfusate K^+ content can be replaced with Rb^+ with no effects on function. ^{87}Rb NMR spectroscopy can be used to determine rate constants for the uptake of Rb^+ on switching from Rb^+ -free to Rb^+ -supplemented perfusate. The converse, switching from Rb^+ -supplemented to Rb^+ -free perfusate, can be used to determine the rate constant for Rb^+ washout. This approach has been used to demonstrate that under normal conditions the bulk of Rb^+ uptake occurs through the Na^+K^+ ATPase rather than the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ exchanger or K^+ channels. ^7Li NMR spectroscopy has been used in similar types of experiments to study Na^+ channel activity in intact hearts. For these studies, an excellent signal could be achieved by substituting a modest amount of perfusate Na^+ with Li^+ (15 mM). Similar to the ^{87}Rb studies, the kinetics of release of Li^+ could be determined in washout experiments. These studies demonstrated that Li^+ efflux from cardiomyocytes is predominantly through Na^+ channels.

Studies of Isolated Livers

Livers isolated from rats or mice may conveniently be studied by NMR spectroscopy. The organs are perfused through the portal vein with solutions similar to those described for isolated heart studies (supplemented with albumin). The methods described above for ^{31}P and ^{23}Na NMR spectroscopy have been successfully applied to the isolated liver. The ^{31}P NMR spectrum of the isolated liver differs from the heart spectrum in that it lacks the PCr peak observed in spectra obtained from hearts. This technique has been utilized to examine various aspects of ethanol metabolism in the liver, including the effects of chronic ethanol exposure on subsequent acute ethanol exposure and hypoxia. These studies revealed that chronic ethanol exposure caused an adaptation in the liver such that it becomes more resistant to acute ethanol exposure and also to hypoxia.

^{15}N NMR spectroscopy has been used to study the urea cycle in isolated liver. ^{15}N was provided to the liver in the form of $^{15}\text{NH}_4\text{Cl}$ or ^{15}N alanine in the presence and absence of unlabelled lactate or ornithine. Proton-decoupled spectra were obtained from the intact liver, from the perfusing medium or from tissue extracts and yielded peaks corresponding to glutamine, arginine, urea, citrulline, glutamate, alanine and ammonia. Such studies may prove to be useful in the *in vivo* liver as a means of assessing the effects of disease states on urea cycle activity.

Studies of Isolated Kidneys

Kidneys isolated from rodents are suitable for study by NMR spectroscopy following cannulation of the renal artery and perfusion with an albumin-supplemented Krebs–Henseleit solution. Combined ^{31}P and ^{23}Na NMR spectroscopy has been used to determine the energetic cost of Na^+ transport in the kidney. Similar multinuclear techniques have been used in studies investigating the factors influencing renal function during the progression from pre-hypertension to hypertension in a spontaneously hypertensive rat model. ^{31}P NMR spectroscopy has been applied to studies into the viability of kidneys used for transplant. At present, donor availability is the limiting factor for transplant programmes. As the use of non-heart-beating donors increases, there is a greater need for a rapid, reliable noninvasive technique for assessing organ viability. ^{31}P NMR spectroscopy is showing promise in this regard.

Introduction

This article discusses the ways in which the design of instrumentation for positron emission tomography (PET) has evolved to provide data with ever greater accuracy and precision. Even though a PET tracer may be intrinsically capable of providing highly specific biochemical and physiological information, this is of little use if the radiation detection system is inadequate. The central aims of PET instrumentation are to increase the number of unscattered photons detected, making maximum use of the amount of tracer it is permissible to administer, and to resolve with greater accuracy their point of origin. A complementary aim is to reduce statistical noise in the data. In addition, developments in the measurement of tracer in the blood are important. A central component of quantification in PET is the combined use of tracer input to the tissue (arterial blood) and tissue uptake (determined from the image). Later in the article a brief discussion will be made of the methods used to obtain physiological, biochemical and pharmacological parameters using different mathematical models of the biological system under investigation.

Detector Materials and Signal Readout

The overall aim in the search for new detectors is to maximize photon stopping power (efficiency) and the

signal generated and to minimize response time. The latter property is required to cut down losses due to dead time or the time during which the detection system is 'busy' dealing with one interaction and thereby misses others that might occur. Theoretical predictions can be made of these properties for different materials, but good detectors have generally been found by a process of trial and error. The dominant detector material in PET today is bismuth germanate ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$, or BGO for short), although sodium iodide (NaI(Tl) , activated with thallium) is still quite widely used. A comparison of the principal properties of these substances and those of a promising material (lutetium orthosilicate, LSO) is shown in **Table 1**. LSO is very attractive because it has a similar density to BGO but also has about five times its scintillation efficiency and a very much shorter scintillation decay time. In consequence, its energy resolution and timing resolution are higher.

The method by which the response of a detector is recorded and analysed (the 'readout') has undergone several developments, and refinements are still being made. Most PET tomographs at present utilize the BGO block detector, a device introduced in the mid-1980s. This was revolutionary in the sense that it enabled a multiple-ring tomograph to be produced at a reasonable cost. Earlier designs had utilized one-to-one coupling of crystal and photomultiplier (PMT), but the multiplicity of coincidence circuits had restricted commercial scanners to at most two detector rings. Furthermore, because of the desire to reduce detector size, the dimensions of

Table 1 Characteristics of some scintillation detectors used in PET

Property	Sodium iodide (NaI(Tl))	Bismuth germanate (BGO)	Lutetium orthosilicate (LSO)
Density (g cm^{-3})	3.7	7.1	7.4

Figure 1 Principle of the block detector.

readily available PMTs made one-to-one coupling impractical. The schematics of the block detector are shown in **Figure 1**.

A BGO crystal is divided into a number of elements (in modern scanners 8×8 with dimensions $4 \times 4 \text{ mm}^2$ face $\times 30 \text{ mm}$ depth) which are viewed by four relatively large, standard PMTs. The cuts between the elements contain light-reflecting material and are made to different depths across the crystal. This partial separation controls the amount of scintillation light reaching the PMTs and leads to a ratio of signals characteristic of each detector element. The x and y coordinates of the interaction are calculated by the formulae given in **Figure 1**. A ring of such block detectors would constitute eight rings of closely packed detector elements and multiple rings of blocks can be placed adjacent to each other to give the desired field of view (FOV) (within financial constraints). With this arrangement, the degree of multiplexing of signals is greatly reduced. On the other hand, the block detector has poorer dead-time properties than an individual crystal-PMT pairing. When one element is hit by a photon, all other elements are effectively 'dead' until the original interaction has been analysed. In some experimental systems avalanche photodiodes (diode detectors with internal amplification) are used instead of PMTs. Their availability and performance still does not

compete with those of PMTs, but their great advantage is their very compact size and ability to view small detector elements.

Full collection of scintillation light from a photon interaction results in a charge pulse from the PMT output whose height is proportional to the energy deposited. The timing of a given event is determined by the point at which the pulse crosses a certain voltage level. The statistical nature of pulse generation and the range of pulse heights encountered give rise to a spread or uncertainty in this timing. An ingenious electronic device known as the constant fraction discriminator greatly reduces this spread by shaping the pulse so that triggering is made at a constant fraction of the pulse height. The rise and fall of scintillation light determine timing resolution τ (how accurately the time of a single interaction can be determined) and integration time (how much time is required to measure the scintillations produced and hence energy deposited). For BGO, the timing resolution is about $6 \times 10^{-9} \text{ s}$ (6 ns) and the integration time is about 10^{-6} s (1 μs). The time spectrum of two detectors (the measured time differences between the arrival of two events) shows a peak superimposed on a constant background (for a given activity). The peak corresponds to true coincidences and the background to random coincidences. The detection of coincidence events involves a convolution of the timing resolutions

Figure 2 Shape of the energy spectrum from a BGO detector for monoenergetic 511 keV photons (—) and those from a scattering medium (---).

of each detector and the coincidence timing window is thus set at twice the timing resolution (i.e. 2τ). If this window is made narrower, the random events will fall linearly but the true events will decrease more rapidly. It is observed experimentally that a window of 12 ns is optimum for BGO detectors.

Even if a beam of monoenergetic 511 keV photons is incident on a crystal, the different scattering and absorption interactions occurring lead to different amounts of energy being deposited and result in output signals with a range of intensities. **Figure 2** is a sketch of the energy spectrum from a BGO detector. The photopeak at the right represents events that have been totally absorbed (photoelectric effect), while the broad continuum corresponds to partial energy deposition (Compton scattering). If the source is within a scattering medium such as the body, the scattering region of the spectrum will be enhanced and the photopeak depressed. The width of the photopeak or the energy resolution (full width at half maximum, FWHM) is about 120 keV for a BGO block detector. (It is only about half this for an uncut block owing to better light transference to the PMT.) In a similar way as for the timing spectrum, the acceptance of events is restricted by setting an energy window of about $2 \times \text{FWHM}$ (about 350–650 keV). This scheme attempts to minimize detection of incident scattered (lower energy) photons but, although BGO has high stopping power, its scintillation efficiency and hence energy resolution is relatively poor and a fraction of scattered photons are inevitably accepted. Methods for subtracting these events are discussed later in this article.

2D and 3D Acquisition Modes

The great advantage of annihilation coincidence detection is the automatic or 'electronic' collimation that it provides, but scattered photons are an ever-present complication, the

Figure 3 (a) Arrangement of inter-ring septa in multi-ring scanners. (b) Axial cross section of a multiple-ring tomograph illustrating inter-ring coincidence combinations for 2D and 3D modes.

effects of which need to be minimized. The first PET tomographs consisted of 'area' detectors such as the large sodium iodide crystals of gamma cameras that were already a standard device for radioisotope imaging. However, it became clear that such scanners had a high sensitivity to scattered photons and random coincidences. Subsequent designs were based on rings of individual detectors with tight collimation using lead shielding. The first commercial scanner comprised a single ring of NaI(Tl) crystals with variable lead collimators in front of the detectors and heavy shielding on either side of the ring. Multiple-ring designs arose from the inevitable demand for a larger axial FOV and in these a form of side shielding known as septa, consisting of lead or tungsten annuli, were inserted between the rings as shown in **Figure 3a**. In such an arrangement, data are acquired as a number of contiguous transaxial 'planes' or 'slices' and it is, for this reason, termed the '2D mode'. Each plane consists of data from coincidences either within an individual ring or in closely adjacent rings. The example given in **Figure 3b** shows a maximum ring difference ($rd_{\max}$) of 1, but, as axial detector width became

narrower to improve resolution, greater values of $rd_{\max}$ were used in order to maintain efficiency. However, it can be seen that for large ring differences coincidence counts would be severely attenuated by the septa (as shown by the dotted line). The approach to statistical image noise has emphasized the importance of maximizing detection efficiency. The restriction of data to '2D' slices tends to go against this and so there were increasing moves during the 1990s to acquire data without septa inserted and with all possible coincidence lines-of-response (LORs) operational. Such a scheme is naturally known as the '3D mode'. Objections to 3D PET scanning stem, of course, from the original desire to reduce the effects of scattered and random coincidences, but the proponents of the method point to the significant increase in the efficiency of detection of unscattered true coincidences. For example, with a tomograph having eight crystal rings and a 2D $rd_{\max}$ of 1 (**Figure 3b**), the total number of inter-ring combinations is 22 (8 direct + 2×7 cross), whereas for 3D the number is 64 (8×8). This threefold increase is further enhanced (by about a factor of 2) owing to 'shadowing' of the crystals by the septa.

This simple analysis is appropriate at low count rates when random events are negligible, but at higher rates the advantage must be defined in terms of improvement in statistical noise as embodied in the parameter noise-equivalent counts (NEC). It is found that there is an NEC gain with the 3D mode over the whole range of count rates. For brain studies this varies from about a factor of 5 at low rates (for example, in receptor binding studies with ^{11}C -labelled compounds) to about 3 at high rates (such as are encountered in blood flow studies with ^{15}O -labelled water).

Data Handling and Image Reconstruction

In addition to the reticence concerning the 3D mode on physical grounds, there are practical challenges. Hardware designed to process coincidence events runs at rates sufficiently high to accommodate the tracer doses that can be administered, but a principal problem is one of data transfer, storage and reconstruction. 2D data are 'compressed' into a number of slices, while 3D data are conventionally acquired without any (or relatively little) compression. The increase in the number of (individual) LORs approaches an order of magnitude and these have to be backprojected during reconstruction and stored. However, despite these perceived disadvantages, the storage and archiving media (multi-gigabyte hard disks, DAT tape, optical disks etc.) and ever faster processors available today have lessened the practical burdens of 3D scanning.

A feature of data acquisition that is becoming of greater interest in PET is that of list mode. In this, the

events are not stored over preselected time frames in the sinogram data matrices but instead each event is stored separately to disk. If a large number of counts are acquired over a short time, this is not necessarily an efficient method, but for studies following the uptake and clearance of tracer for 2 hours or more, it becomes much more efficient. However, even for shorter scanning times, list mode provides very high temporal (≈ 1 ms) resolution and the ability to utilize physiological gating, or separation of the data into specific phases, for example of the cardiac and respiratory cycles. Furthermore, list mode acquisition would be of great advantage in the correction for patient movement.

Dedicated processing hardware can reconstruct a set of images from the largest 3D PET data volume rapidly but the ability of tomographs to acquire data in 3D mode somewhat preceded the development of appropriate reconstruction algorithms. The specific problem with filtered backprojection lay in the variation of the point response function (PRF). Reconstruction of 2D slices relies on the fact that the response to a point source (efficiency of detection) remains constant over the slice. This requirement needs to be met because the filtering process represents a convolution with the measured projection data. In the 3D mode the PRF is not constant over the FOV, being a maximum in the centre and falling steadily (axially) towards the edge (**Figure 4a**). A way of overcoming this difficulty, and one that is now commonly used, is the reprojection method. In this (**Figure 4b**), 2D images are first reconstructed from direct plane (single ring) data and then 'missing' projections are created by forward projection (images to views). The missing projections are those that would have been acquired if additional detector rings had been present and these complement the data to provide an invariant PRF over the (original) FOV.

Alternative Tomograph Designs

Tomographs consisting of multiple rings of individual crystals are the most widely used. **Figure 5** shows the CTI/Siemens model 966 (covers removed), however, there are a number of other designs in operation.

Tomographs Based on Planar Sodium Iodide Detectors

Large-area planar sodium iodide (NaI(Tl)) detectors, which are used routinely in gamma cameras for imaging of single-photon tracers, saw a revival in PET in the 1990s. A commercial design consists of six planar detectors arranged in a hexagon and operated without septa (3D mode). The crystal is viewed by an array of PMTs and the point of photon interaction is determined, in a similar way to the block detector, by comparing signals

Figure 4 (a) Variation of point response function (PRF) in a multiple-ring tomograph. (b) Creation of 'missing' projections for the reprojection reconstruction algorithm.

Figure 5 A commercial PET scanner.

between adjacent tubes. This device takes advantage of the high light output (Table 1) of NaI(Tl) and possesses a similar spatial resolution to BGO systems. On the other hand, its stopping power (efficiency) is significantly less than that of BGO. Indeed, the standard detector thickness used for single-photon imaging (at about 100 keV) of about 10 mm is increased to 25 mm for the 511 keV photons in PET. One advantage of this system is that large NaI(Tl) crystals can be produced at relatively low cost, giving a large FOV. This aspect and the availability of the glucose analogue tracer [^{18}F]fluorodeoxyglucose (FDG, see later for clinical diagnostic imaging) have been responsible for its commercial success.

There is also increasing interest in 'dual-use' systems for both single-photon emission tomography (SPECT) and PET, consisting of double-headed gamma cameras (operated with and without multihole lead collimators,

respectively). The significantly lower efficiency for PET compared with purpose-built tomographs needs to be borne in mind, but such systems could be useful for specific diagnostic tests (e.g. detection of tumour metastases) and their flexibility for general nuclear medicine use is attractive.

Partial-Ring Tomographs

As alluded to above, the expense of multiple-ring BGO tomographs has led to the development of lower-cost systems, principally those employing NaI(Tl) planar detectors. An alternative to these is the commercially available partial-ring scanner. In this device, two banks of BGO detector blocks (about 1/3 of a complete ring) rotate around the body (at 30 revolutions per minute) and the output of data is achieved via optical coupling. Voltage supplies are provided through slip rings.

Tomographs Based on Multiwire Proportional Chambers

The multiwire proportional chamber (MWPC) is a device used extensively in high-energy particle physics experiments that has been modified in different ways for use in PET. The principle of operation is the detection of an electron (i.e. an electron avalanche) on planes of closely spaced fine wires (~ 1 mm apart) held at a high electric potential. Cathode and anode wires are arranged orthogonally to each other, thus providing the spatial localization, the wire spacing being the basic determinant of resolution. The electrons are produced in various ways, such as interaction of photons in thin sheets of lead or photoionization of a gas in the wire chamber by ultraviolet light from a barium fluoride (BaF_2) scintillator.

Tomographs for Experimental Studies

A number of research centres have designed and implemented smaller-diameter tomographs (BGO, NaI(Tl) and multiwire chamber detectors have all been used)

specifically for the scanning of small animals. Spatial resolution close to 1 mm has been achieved. Although this does not compete with the resolution of autoradiography or dissection, the time–activity curve can be followed in a single animal, which is a great advantage in many studies, such as the investigation of new tracers and the testing of models of disease processes. It is anticipated that important new information will also be forthcoming in the development of new pharmaceuticals.

Data Correction Procedures

Normalization

Variations in the fabrication of detectors and their geometrical arrangement in a tomograph inevitably lead to variations in efficiency for different LORs. For example, the detectors at the edge of a BGO block have lower efficiency than those at the centre and the LORs crossing the centre of the FOV will have a different solid angle of detection to those at the edge. If these effects are not corrected for, systematic errors (of both high and low spatial frequency) will occur in the reconstructed image. The process of correction is known as normalization. The basic data for normalization are acquired by exposing each LOR to the same activity, for example in the form of a thin planar source or a line source scanning across the FOV.

Attenuation

The principles of attenuation and its correction in PET are outlined in an associated article. Here, some specific practical examples are given. Most PET tomographs utilize sources of ^{68}Ge (half-life about 9 months), which are stored in shields within the gantry of the tomograph and moved into the FOV by remote control. In turn, a blank scan (empty FOV) and a transmission scan (patient in position, usually before tracer administration) are acquired. The ratio between these two provides the attenuation correction factors for each LOR. The logarithm of these ratios can also be backprojected to yield a transmission image (tissue density map). As for emission data, scattered radiation (see below) contaminates the data and one method of reducing this is electronic ‘windowing’. This is illustrated in **Figure 6**. The transmission source in this case is a rotating rod whose position is encoded. If a photon from the rod is scattered in the object and measured, the event will be rejected because the resulting LOR (LOR2) does not pass through the rod. Unscattered events (e.g. LOR1) are accepted.

A continuing theme of PET is improvement in efficiency, and this is so for transmission scanning. Constraints of time and detector performance mean that transmission data can be suboptimal and this has led to the implementation of the

single-photon transmission technique. This is similar to the process of X-ray computerized tomography and takes advantage of the fact that about two orders of magnitude more single-photon events are collected than coincidence events. A working mechanism employs a ^{137}Cs point source (single-photon: energy 662 keV, half-life 30 years) rotating in a helical tube around the subject. However, as for the rotating ^{68}Ge source in **Figure 6**, detection of scattered radiation will also contaminate the data in this case and lead to inaccurate correction. Recourse to the windowing method cannot be made for ^{137}Cs , but another way to compensate for scatter is to create a transmission image that is then segmented into regions of similar density, and correct attenuation factors are assigned accordingly.

Scattered Radiation

The inclusion of scattered events in the projection data does not significantly affect the spatial resolution or ‘sharpness’ of the reconstructed image but it will lessen the contrast between different regions and cause inaccuracies in the measurement of activity concentration. The distributions of scatter due to a line source placed axially in the centre of a water-filled cylinder (20 cm diameter) are shown in **Figure 7** for 2D and 3D acquisition modes. The central peak corresponds to the position of the source and the broad continuum (‘wings’) on either side is due to scatter, which decreases with increasing angle. The scatter fraction (SF, integral of the ‘wings’ divided by the total events) for brain scanning is 10–15% with septa and 30–40% without septa; even larger values obviously occur in body scanning.

A number of methods have been used to correct for scatter, particularly for the 3D scanning mode. Correction schemes have broadly been based on the measured spatial or energy distribution (spectrum) of scattered events or, more recently, on calculation from first principles of the probability of scattering through different angles.

The first scatter correction methods, which are still employed, treated the scatter distribution as a convolution of the projection data with a function or ‘kernel’, the shape of which was derived from curves such as that in **Figure 7**. The simplest form of the kernel is $\alpha \exp(-\beta|x|)$, where α and β are positive constants and $|x|$ is the absolute distance along a projection. In general, convolution is carried out iteratively because the measured projections contain scatter and so the initial calculation is an overestimate. A shortcoming of the simple kernel above is that the shape of the scatter distribution does not stay constant with the position of the source. As it moves to one side of the object, the distribution becomes more and more asymmetric. Strictly, in this case, an integral transform rather than a convolution should be employed since the kernel shape is position dependent. However, quite accurate

Figure 6 Mechanism for attenuation correction using a rotating ^{68}Ge rod with 'windowing'.

Figure 7 Scatter distributions for a line source in the centre of a cylinder (2D and 3D); peaks are normalized to the same height.

scatter corrections for the head have been demonstrated, even in the 3D mode, with an invariant kernel.

A correction method based on the photon energy spectrum utilizes the varying proportions of scattered and unscattered events for different ranges or energy windows. This technique had its origins in single-photon tomography. Some PET tomographs have the ability to acquire data in two energy windows (over the photopeak and over part of the Compton continuum). A simple form of the dual-window correction is based on the assumption that the ratios are constant throughout the object. The dual-window method has been shown to give similarly accurate corrections (within about 6%) to the

convolution method in 3D brain scanning but has slightly poorer noise characteristics.

The simplest method of scatter correction consists of fitting a function (typically a Gaussian) to the 'wings' (pure scatter) outside the object. This has the advantage of being based on a direct measurement of scatter for each object. On the other hand, assumptions must be made about the shape of the distribution *inside* the object. Again, accurate results are obtained for the head, but for the chest a simple Gaussian is not necessarily a good choice of function.

The speed of current computers has made it feasible to calculate scatter distributions analytically from first principles for each set of data. This is carried out by taking the uncorrected tracer (emission) image and calculating the scatter that would arise from selected points given the transmission image. The probabilities of scattering through given angles are known precisely from physical principles. In practical implementations, a relatively coarse grid of points is selected. This saves time and utilizes the fact that the scatter distribution is smooth and is amenable to interpolation. The beauty of this technique is that it makes few assumptions. Convolution and dual-window methods work well in a relatively uniform object such as the head but have more difficulty, for example, in the chest where there are abrupt density changes. A big challenge for PET is to obtain accurate quantification in 3D body scanning and it is likely that analytical methods such as this will prove the most valuable.

Dead Time and Random Coincidences

As the activity in the body increases, the problems of electronic dead time and registration of random coincidences,

Figure 8 (a) The variation of measured trues and randoms with activity in the FOV. (b) The correspondence between 'ideal' trues rates (extrapolated from low activities) and dead time-corrected trues.

leading to a reduction in efficiency and an increase in statistical noise, become ever more pressing.

Dead time correction schemes have ranged from those that are founded on an intimate knowledge of the electronic circuitry of the scanner to those based on empirical curve-fitting using test objects. All commercial scanners provide automatic dead time correction. The variation of true and random coincidences with activity is shown in **Figure 8a**. The peak and steady falloff in the trues curve at high rates is described as paralyzable dead time behaviour and is typical of PET tomographs. In this case, if an event occurs during the analysis of a previous event ('busy' period), the effect is a successive lengthening of the dead time. Theoretically it can be shown that measured (N_m) and corrected (N_0) count rates are related by

$$N_m = N_0 \exp(-N_0 \tau_d) \quad [1]$$

in which case the measured rate can eventually go to zero (or be 'paralysed') for very high activities (τ_d is the system dead time). The fundamental determinant of dead time is the rate of single events that are striking the detectors. Tomographs continuously record this rate and use it as a basis of the calculation of dead time correction factors. It should be noted that, for coincidence counting, the overall dead time is the *product* of the dead times of opposing detectors. Generally speaking, correction is accurate to within 5% for the range of counting rates encountered in *in vivo* studies (**Figure 8b**), but it needs to be stressed that the magnitude of the correction factor should not be too large and that scanning should not be carried out near to or beyond the peak of the 'trues' curve.

The steep rise in random events with activity is, similarly to dead time, due to the product of the rates of single events on opposing detectors. Without dead time, trues rise linearly with activity, whereas randoms rise quadratically (the dead time for trues and randoms is the same because they are counted by the same coincidence circuits). This behaviour of randoms means that judicious administration of activity should be adhered to and/or good shielding of activity outside the FOV should be provided. The move towards 3D PET and the desire to accommodate any part of the body and to increase the axial FOV pose problems in this regard. The dilemma can be illustrated by simple geometry (**Figure 9**). The largest axial FOV for a multi-ring tomograph is about 25 cm (left of **Figure 9**). With standard side shielding giving an aperture of 60 cm diameter, the FOV for single photons extends about 75 cm beyond the coincidence FOV. With the insertion of additional shielding appropriate for the brain (an aperture of 35 cm), the single-photon FOV is reduced significantly. The more common axial detector length of about 15 cm clearly gives a much reduced single FOV, which for brain scanning barely extends beyond the side shielding. Providing effective shielding for body studies is not easy, but a way of processing the random events in order to lessen their effect is to apply some form of smoothing. As for scatter, the distribution of randoms is of a broad, low-frequency nature and thus amenable to smoothing. The future alternative to this is to use detectors with faster response, narrower coincidence window and proportionately lower randoms.

Spatial Resolution Effects

The spatial spread of a point source in an image gives rise to a phenomenon known as spillover, in which activity in one region affects that measured in an adjacent region. A source of decreasing size in a 'background' of lower activity concentration will appear to have decreasing activity. This is purely an effect of finite resolution and

Figure 9 The change in FOV for single events for different detector ring diameters and axial lengths.

Figure 10 Variation of spatial resolution in radial and tangential (at right angles) directions with distance from the centre of the tomograph FOV.

not of efficiency and is often referred to as the partial volume effect (that is, the object only partially fills the detector resolution field-of-view and is 'mixed' with its surroundings); it is also expressed by saying that the recovery coefficient of the object is less than unity. This is a difficult problem, but one correction technique that has been applied in the brain relies on the much higher resolution of a magnetic resonance image to provide accurate anatomical data.

Coincidence detection gives good uniformity of resolution along an LOR, but for circular ring systems the resolution in the radial direction gradually worsens owing to the interaction of photons with detectors at increasingly oblique angles (**Figure 10**). This effect is magnified as the ring diameter decreases. The desire for smaller diameters (and hence less expensive systems) requires a remedy for this non-uniformity. A number of methods of correction are being tested, such as the dual use of photodiodes and PMTs on either ends of a detector, but no one method has yet gained general acceptance.

Figure 11 Three-compartment tracer model.

Models of Tracer Kinetics

Even if all physical corrections have been applied and the image is an accurate representation of tracer distribution, the further big challenge in PET is to derive biochemical, physiological and pharmacological parameters from the data. This is carried out by diverse mathematical models of the biological system. What may be termed a conventional approach is to treat the system as a number of separate compartments within each of which the tracer is uniformly distributed. The passage of tracer between compartments is described by rate constants that have dimension per unit time (time^{-1}). An example of such a system is shown in **Figure 11**, which divides the volume under investigation into blood (plasma) and free and fixed tracer in tissue. In PET research blood activity is usually measured either by taking discrete samples or by on-line monitoring in a detector placed by the side of the patient. A refinement of this is analysis of the blood into different radioactive components or metabolites because the tracer itself is broken down in its passage through tissue.

A compartmental model describes the system by a number of differential equations from which the rate constants are estimated. A common application of the model in **Figure 11** is in the dynamics of glucose utilization. The most widely used tracer in PET is an analogue of glucose known as FDG (^{18}F -labelled fluorodeoxyglucose). It is transported into the cell and undergoes the biochemical process of phosphorylation similarly to glucose, but it then remains 'trapped' in the tissue. Because of this, good quality images of glucose utilization can be obtained. Over the period of a study (an hour or so), there is negligible release from the fixed compartment (k_4 in **Figure 11** is negligible) and this simplifies the model. In this case, the metabolic rate for glucose (MRGI) is given by

$$\text{MRGI} = \frac{C_p k_1 k_3}{\text{LC}(k_2 + k_3)} \quad [2]$$

where C_p is the (natural) glucose concentration in the plasma and LC is a constant that describes the difference in transport and phosphorylation rates between FDG and glucose. Examples of functional images of MRGI (two slices through the brain) are displayed in **Figure 12** (left) along with magnetic resonance (MRI) images showing anatomical detail (right) and coregistered PET and MRI images (centre). Coregistration covers a number of techniques used to overlay functional and anatomical images which, for example, make use of specific anatomical markers or the minimization of the variance between the two images.

Other types of tracer model do not seek to impose a compartmental structure but instead determine a combination of kinetic components which best fit the data.

For example, the technique of spectral analysis views the tissue response (C_{tiss}) as a convolution between the plasma/blood input (C_p) and a large but finite range of so-called basis functions of the form $\gamma \exp(-\delta t)$, where t is time:

$$C_{\text{tiss}}(t) = C_p(t) \otimes \sum_{j=1}^{j=n} \gamma_j \exp(-\delta_j t) \quad [3]$$

When the γ_j are fixed and the δ_j are constrained to be zero or positive, it transpires that typically only two to four positive δ_j are needed to define for the time-activity curve on each image pixel. The resulting parameters are used to generate the impulse response function (the tissue time-activity curve resulting from a unit pulse input at $t = 0$). The intercept of this function (for each pixel) at $t = 0$ gives an image of the clearance of tracer from blood to tissue (denoted K_1) and its integral gives the volume of distribution (concentration in tissue relative to blood, denoted V_d).

Frequency analysis is an example of a more objective way of extracting kinetic information from PET time-activity data. Other forms of this are factor, principal components and cluster analyses. These attempt to define pixels in the projection or image data that have similar kinetic characteristics. Their fundamental aim is the derivation of more specific and objective images of function rather than purely radioactivity concentration, a task that is enhanced by the superior physical properties of positron annihilation coincidence detection.

Symbols

A_T	number of photons left unscattered after distance T along the LOR
A_o	original number of photons
c	speed of light
E_o, E_f	initial and final energy of scattered photon
f	fraction of FOV subtended by the object
m_o	rest mass of the electron
N	total number of counts (trues)
N_{re}	number of resolution elements
N_x	number of unscattered photons at x
P	number of prompt events
r	detector radius
R	number of random events, detector ring radius
S	total number of scattered events
t	detector width (axial thickness)
T	distance along LOR, coincidence time window
T_{tot}	total number of true (unscattered + scattered) events
Δd	sampling distance = spacing between adjacent LORs
Θ	scattering angle of photon
μ	attenuation coefficient
τ	timing resolution

Introduction

The acronym PET can be used to stand for both positron-emitting tracers and positron emission tomography; it is a representation of the radioactive isotopes used and the methods by which their distribution is visualized (tomography derives from the Greek tomos or ‘cut’ – i.e. an imaged slice through the body). PET is the most sensitive and specific method of studying molecular interactions and pathways in the living organism and is assuming ever greater importance in medical diagnosis and research, in the understanding of biochemistry and physiology in health and disease, and in the development of drugs. Most of the world’s PET centres are in North America, Europe and Japan, but many other countries are making plans for the installation of PET facilities. Most of the centres are dedicated to diagnosis,

particularly in heart disease and cancer, but there are also a number of centres associated with large medical research institutes that concentrate purely on research. This article will deal with the theoretical aspects of PET: (a) isotope production, (b) radiation interactions and detection, (c) data acquisition and image formation and (d) properties of the image of radioisotope distribution.

Physics of the Positron

A positron (positively charged electron) is a particle of so-called ‘antimatter’ that cannot coexist for long with the ‘ordinary’ matter of which we and all that surrounds us is made. Such particles were postulated in the 1930s by the physicist Paul Dirac, who pictured the vacuum as a ‘sea’ of electrons in negative energy levels that could be excited into positive energy levels by the absorption of quanta of energy. Although this concept was not readily accepted by most physicists, the existence of the positron was demonstrated experimentally by Anderson three years after the theoretical prediction. It was observed that a photon, of energy greater than or equal to twice the rest mass energy of the electron, in the field of the nucleus could give rise to the simultaneous appearance of a positron and an electron. This is known as the pair-production process. The positrons used in PET, however, arise from the disintegration of atomic nuclei that are unstable because they have an ‘excess’ of positive charge.

Production of Positron Emitters

Positron-emitting atoms do not normally exist in nature. The radionuclides used for PET are usually produced by a cyclotron, which, by harnessing powerful electric and magnetic fields, accelerates charged particles (such as protons, deuterons or alpha particles) to high energies (about 2–5% of the speed of light); these then bombard stable atoms in a target to give rise to radioactive isotopes. **Table 1** gives examples of the reactions used to produce the principal radionuclides used in PET (^{11}C , ^{15}O , ^{18}F and ^{13}N). It can be seen from column 3 that there are generally more protons than neutrons in each of the product nuclei. This ‘excess’ charge is released during nuclear disintegration (beta decay) by the emission of a (positively charged) positron (or in a smaller fraction of

Table 1 Production and characteristics of principal isotopes used in PET

Positron-emitting product	Stable element	Nuclear reaction	Number of protons (<i>p</i>) and neutrons (<i>n</i>) in the product nucleus	Half-life of product (min)	Stable nucleus after positron emission
^{11}C	Nitrogen (^{14}N)	$^{14}\text{N}(\text{p},\alpha)^{11}\text{C}$	6p, 5n	20.4	^{11}B
^{18}F	Oxygen (^{18}O)	$^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$	9p, 9n	109.8	^{18}O
^{15}O	Nitrogen (^{14}N)	$^{14}\text{N}(\text{d},\text{n})^{15}\text{O}$	8p, 7n	2.03	^{15}N
^{13}N	Carbon (^{12}C)	$^{12}\text{C}(\text{d},\text{n})^{13}\text{N}$	7p, 6n	10.0	^{13}C

Table 2 Positron ranges in soft tissue for the principal positron emitters

Positron emitter	Positron energy (MeV)		Positron range in soft tissue (mm)		Contribution to resolution (mm FWHM)
	Maximum (E_{max})	Mean	Maximum	Mean	
^{18}F	0.635	0.250	2.6	0.61	0.2
^{11}C	0.970	0.386	4.2	1.23	0.3
^{13}N	1.200	0.491	5.4	1.73	0.4
^{15}O	1.740	0.735	8.4	2.97	1.2

cases by the capture of an orbiting electron). Two principal characteristics of the positron emitters in **Table 1** that are responsible for their success as *in vivo* radio-tracers are that (a) they are radioisotopes of major body elements (or in the case of ^{18}F serve as *in vivo* analogues) and (b) they have short half-lives. These properties enable them to be used as labels in biological molecules without altering the biochemical action and to be injected into a patient or normal volunteer in usable quantities with an acceptably low radiation dose. The physical characteristics of detection of these tracers, which will be described below, provide additional reasons for their pre-eminence in nuclear medicine. However, the short half-lives demand that the scanner (tomograph) and cyclotron are in close proximity. Such a necessity has given rise to the impression that PET is an expensive technique, but an increasing number of clinical centres are obtaining tracers from shared central cyclotron facilities and lower-cost scanner designs are commercially available.

Positron Annihilation

Positrons are emitted from nuclei of a given isotope with a range of energies up to a characteristic maximum 'end point' energy E_{max} (**Table 2**), the mean energy being roughly one-third E_{max} . Positrons lose their energy by Coulomb interactions with atomic electrons, following a tortuous path until they are brought to rest within a precisely defined range (dependent on their energy and the effective atomic number of the medium). The ranges for mean and maximum energies in soft tissue are given in **Table 2**. When the energy of the positron is close to zero, the probability of interaction with an electron is highest. From direct interaction or after the formation of

a transient system with an electron known as positronium, two photons, each of energy 511 keV (the rest mass energy of the electron or positron), are emitted in opposite directions with the disappearance (annihilation) of both particles. The 'back-to-back' photon emission arises from the conservation of momentum. However, there is only precisely 180° between the photon directions if the net momentum is zero at annihilation. The small residual momentum of the positronium system leads to an angular spread of about $\pm 0.3^\circ$. Positron range and the angular spread determine the physical limits of spatial resolution in PET.

Annihilation Coincidence Detection

Simultaneous detection of the annihilation photons provides significantly greater efficiency and improved uniformity of spatial resolution than detection of individual photons. These points are illustrated schematically in **Figure 1**. Consider a point source positron emitter in air moving across the channel between the two detectors D_1 and D_2 (**Figure 1a**). The channel is conventionally termed a 'line-of-response' (LOR) and the detectors are connected such that a 'count' is only registered when a photon interaction is recorded in each detector at the same time (or within the time resolution of the detector, see below). Only when the source is within the LOR (e.g. position P_1) do annihilation photons such as γ_1 and γ_1 have a chance of being detected as a coincident pair. With the source at position P_2 (e.g. photons γ_2 and γ_2), there is no possibility of a coincidence event. Therefore, coincidence counting confers a natural collimation of the radiation, often referred to as electronic collimation and, in addition, the resolution varies relatively little for different positions along the LOR. The variation in counts

Figure 1 (a) Annihilation coincidence and (b) single-photon detection.

obtained by passing a point or (orthogonal) line source across the LOR is termed the point or line spread function (PSF, LSF) and is conventionally characterised by its full-width at half-maximum (FWHM). The PSF obtained in this way represents the intrinsic resolution of the detector pair, in other words, the best achievable.

To obtain spatial localization with a source emitting only single photons (γ rays from nuclear disintegration), a physical (lead) collimator has to be placed between source and detector D (Figure 1b). The solid angle subtended by the collimator aperture shows that the resolution in this case will vary with distance from the detector. The aperture can be made smaller to give a spatial resolution as high as desired, but this will be at the expense of detection efficiency and so some compromise is needed. Single-photon emission tomography (SPECT) systems normally consist of large-area detectors, whereas most modern PET systems consist of thousands of coincidence detector pairs and the detection efficiency in PET is about 100 times that of SPECT.

Photon Interactions and Attenuation in Scattering Media

The previous discussion of coincidence detection becomes more complicated when the source is within a scattering medium (such as body tissue). At the energy of

the annihilation photons (511 keV), the possible interactions (with atomic electrons) are photoelectric (total absorption and coherent and incoherent (Compton) scattering. Scattering refers to change of direction without (coherent) or with (incoherent) energy loss. Compton scattering is overwhelmingly predominant at 511 keV in the body (the probability of photoelectric absorption and coherent scattering can be considered negligible) and is thus, practically speaking, totally responsible for the removal of a photon from a particular LOR. This is termed attenuation and is illustrated in Figure 2a. If the scattering medium is uniform, it will have a constant attenuation coefficient (μ), dependent on the effective atomic number, defined as

$$dN = \mu N_x dx \quad [1]$$

where dN are the number of photons scattered within a distance x to $x + dx$ and N_x is the number of unscattered photons at x . Integrating eqn [1] gives the following formula for the number of photons (A_T) left unscattered after a distance T along the LOR:

$$A_T = A_0 \exp[-\mu T] \quad [2a]$$

If the attenuation medium is not uniform, then eqn [2a] is modified to give

$$A_T = A_0 \exp\left[-\sum_i \mu_i \Delta T_i\right] \quad [2b]$$

Figure 2 Photon attenuation in a given LOR due to Compton scattering.

where μ_i = the attenuation coefficient within a small element ΔT_i .

Equation [2] describes what is known as ‘narrow beam’ attenuation because if one is just interested in the LOR between two detectors, a scattered photon is completely lost. For an array of detectors (as in a PET scanner), however, it can be imagined that the scattered photon might be detected in another LOR; this is considered later.

The larger the angle (Θ) through which a scattered photon is deflected (**Figure 3**), the greater is its loss of energy. From simple kinematics (conservation of energy and momentum), the relationship between the initial photon energy E_0 and final energy E_f is

$$E_f = \frac{E_0}{1 + E_0(1 - \cos \Theta)/m_0c^2} \quad [3a]$$

where m_0c^2 is the rest mass energy of the electron (m_0 = electron rest mass; c = the speed of light). Since the rest mass energy is equal to 511 keV, this equation simplifies for PET to

$$E_f = \frac{E_0}{2 - \cos \Theta} \quad [3b]$$

Figure 3 Mechanism of photon (Compton) scattering.

Table 3 Examples of scattering angles and energies in Compton scatter of annihilation photons

Scattering angle Θ ($^\circ$) (see Figure 3)	Energy of scattered photon (keV)	Probability of scatter (%) ($0^\circ = 100\%$)
30	451	68.7
60	341	31.5
90	256	18.8
180 (Back-scattering)	170	18.5

The maximum energy that can be transferred to an electron in this interaction is when the photon is deflected back along its original path (‘backscattering’), that is when $\Theta = 180^\circ$. In this case E_f (minimum) = $E_0/3 = 170$ keV. Some other examples of scattering angles and energies are given in **Table 3**. However, eqn [3] only gives the resultant energy for a given angle; the probability of scattering through a particular angle is described by a much more complicated expression known as the Klein–Nishina formula. The relative probabilities of scattering are shown in the third column of **Table 3** (taking that for 0° as 100%). It can be seen that, even for a relatively large scattering angle, the photon still retains a significant fraction of its energy but that the probability of scattering falls quite quickly with increasing angle.

To obtain an accurate measurement of the regional distribution of isotope concentration in the body, the primary correction is that for attenuation. The basic principles of attenuation correction, relatively straightforward in PET, are as follows. Consider the attenuation lengths a and b on either side of the point source in **Figure 2b**. From eqn [2], attenuation along these two paths will be proportional to $\exp[-\mu a]$ and $\exp[-\mu b]$. For coincidence counting, the total attenuation will be proportional to the product of these two factors: $\exp[-\mu(a + b)]$. This expression is independent of the position of the source along the LOR and indeed would be so if the source were outside the object. If such an external source is measured with and without the (inactive) object in the LOR, the ratio of the measurements

gives the attenuation correction factor along that line. For single-photon detection, it should be noted that attenuation is dependent on depth in the object and this makes correction more complicated. Specific methods of attenuation correction in PET are dealt with in the article entitled PET, Methods and Instrumentation.

Detection of Annihilation Photons

Most PET scanners consist of individual detector elements arranged in a number of adjacent coaxial rings surrounding the patient. Each element is connected in coincidence with a number of other elements in both the same ring and any number of other rings, and modern scanners consist of thousands of detectors and millions of LORs. Specific scanner configurations are given in the article covering Instrumentation and Methods.

Detector materials must have a high atomic number to maximize their attenuation of annihilation photons and must also produce a measurable response. The great majority of detectors used in PET are scintillators, which respond to the absorption of photon energy by the emission of visible light. This occurs when electrons fall from excited energy levels to the ground state, a process often facilitated by the inclusion of a small amount of impurity (or activator) into the scintillation crystal. The light output rises rapidly to a peak and then falls with a characteristic 'decay time' and is converted into an electrical pulse by a photomultiplier tube (PMT) and subsequently amplified. The speed of response of the detector determines the width of this pulse and the precision with which the time of the interaction can be measured – the timing resolution, denoted by τ . In addition, the detector electronics take a finite time to process each event, during which other events go unrecorded. This time is known as dead time and corrections have to be made for accurate quantification. Based on the timing resolution, a coincidence time window is set within which events in two opposing detectors are regarded as constituting a coincidence event. This can be either a true event or a random (chance) event, depending on whether the photons came from the same or different annihilations. These collectively are known as prompt events (events are commonly termed 'prompts', 'trues' and 'randoms'). A distinction can be made between trues and randoms by counting the number of events occurring when the time window for one detector is delayed (by about 100 ns) relative to the other. A coincidence recorded in the 'delayed circuit' cannot be a true coincidence and it is assumed that the 'delayed events' are equal to the randoms recorded in the undelayed ('primary') circuit. Trues are therefore determined by subtracting the randoms from the prompts.

An alternative way of calculating random events is by recording the total rate of single photons striking each detector. If these singles rates for detectors 1 and 2 are S_1

and S_2 , then the rate of random events (R_{12}) between the two detectors is given by

$$R_{12} = S_1 \cdot S_2 \cdot T \quad [4]$$

where T , the coincidence time window, is twice the timing resolution (i.e. 2τ). The distribution of randoms is quite uniform over the field-of-view (FOV) of the scanner but if not subtracted will impair the quantification of regional radiotracer concentration and reduce contrast in the image.

Spatial Sampling and Resolution

One of the continuing aims in PET is to improve spatial resolution or the clarity of definition of isotope distribution in the body. The physical limit of resolution is dictated by positron range and non-collinearity of annihilation photons as outlined above. The ranges of positrons in the body for the most important isotopes are given in **Table 2**. These appear to be rather large, but it should be borne in mind that the contribution of positron range to resolution in the image is reflected in the average range and that positrons travel in all directions and not just orthogonally to an LOR. The net contribution to resolution (FWHM of the point spread function) is given in **Table 2**. The physical limitation imposed by the small angular spread around the 180° ('back-to-back') photon emission leads to an additional 'blurring' of resolution independent of positron energy but increasing with the diameter of the detector array. For a scanner of diameter 80 cm (common for imaging of humans), the fundamental limit imposed by these effects is about 2 mm, whereas for a diameter of 20 cm the limit is less than 1 mm.

To image the distribution of a radiotracer, the active volume must be sampled as finely as possible. In other words, measurements must be made along a number of LORs, as closely spaced as practicable, both across the object and at different angles. The basic property of a tomographic system with good resolution is the ability to distinguish changes in tracer concentration. Another way of expressing this is that the system has a good spatial frequency response. This may be envisaged analytically by presenting a 'bar pattern' of alternating white and black (active/inactive) stripes to the imaging system. As the width of the bars is reduced, there will come a point when the imager will no longer be able to reproduce the pattern; the input (object) frequency will no longer produce a faithful output (image). Mathematically this is expressed in terms of the modulation transfer function (MTF), which gives the fraction of signal amplitude that a system will transfer to the image at each spatial frequency. A broader MTF function will give a sharper resolution.

The requirement of an imaging system is expressed formally by the sampling theorem, which states that the highest frequency that can reliably be measured (known as the Nyquist frequency) is equal to $1/(2\Delta d)$, where Δd is the sampling distance (the spacing between adjacent LORs). One of the principal aims in the design of a PET tomograph is to provide as high a degree of sampling as possible. However, a fundamental limit (apart from positron range and photon noncollinearity) is imposed by the detector width (the intrinsic detector resolution as defined above). Better sampling schemes will deliver an image resolution ever closer to the intrinsic resolution, but this cannot be exceeded without additional 'post-processing' of the image. Early tomographs of the late 1970s/early 1980s with relatively large (~ 25 mm) detectors, which were not densely packed, optimized their sampling by incremental linear and angular motion. Most tomographs in use today consist of circular rings of detectors of width 6 mm or less. For these, adequate linear and angular sampling is achieved without any motion, although in some designs a rotatory motion (known as 'wobble') is incorporated. This has largely been abandoned because the data volumes were increased typically by a factor of 4 without a great improvement in resolution.

The organization of data acquisition in a circular ring of detectors is shown in **Figure 4**. Each detector is connected in a coincidence circuit with a number of detectors on the other side of the ring (**Figure 4a**). (The more general case of multiple rings is discussed in the article on Instrumentation and Methods.) The LORs that are parallel to each other are grouped together to form projections or views of the object at each angle

(**Figure 4b**). The counts recorded in each of these LORs form one row of a data matrix called a sinogram (**Figure 4c**), each row corresponding to an angle of view. In a more recent design, there are 576 detectors in the ring and each detector is in coincidence with 288 other detectors. The number of views in the sinogram in this case is $576/2 = 288$ (each separated by an angle $180^\circ/288 = 0.625^\circ$) and the number of LORs in each view is 288.

Formation of an image can be achieved by a number of different methods, but all of them involve back-projection of the views across the FOV. For practical purposes, the position of an annihilation event along an LOR is indeterminate. Some detectors, notably barium and caesium fluorides, are capable of modest time-of-flight resolution (FWHM ~ 5 cm) by measuring the time difference of the photon interactions, but this has not proved to give significant advantages because of their lower efficiency. The raw process of image formation conventionally divides the 'image space' into a matrix of square boxes or pixels (picture elements) and places 'counts' in each pixel proportional to the counts recorded in the particular LOR and the area of overlap of LOR and pixel. This process is illustrated for a point source in **Figure 5a**. Only a small number of projections, each consisting of a peak corresponding to the source position, are shown for clarity. The back-projected profiles for each projection will intersect at the position of the point source, but the image will be a poor representation of the original because of the 'background' imposed. This may be described mathematically by saying that the high spatial frequency components of the source have been attenuated and low frequencies enhanced. This process is

Figure 4 Geometrical relation between LORs and the sinogram data matrix.

Figure 5 (a) Formation of an image by filtered back-projection. (b) Shape of ramp filter in frequency space and real space.

reversed by frequency filtering in which the Fourier transform is first applied to the projection data to give the magnitude of each component spatial frequency and a filter is applied with increasing weight given to higher frequencies. This filter is accordingly termed a ramp in frequency space. In real space, the form of the filter is as sketched in **Figure 5b**, which shows alternating positive and negative oscillations decreasing in intensity from its centre. When this is convolved with the projections and back-projection is performed, the effect is that the positive and negative components cancel each other out, so removing the low-frequency 'blur' and restoring the high-frequency nature of the object in the filtered image.

Filtered back-projection is the most commonly used method of image formation in PET because Fourier transforms can be calculated rapidly with modern computers. However, the method has its drawbacks and these are intimately allied to statistical variations or noise in the projection data. As the number of counts recorded by the system decreases, so the statistical uncertainty

increases, as described by Poisson statistics, and 'star artefacts' (remnants of the back-projection process) become increasingly apparent. Filtering causes each pixel in the image to be correlated to some degree with every other pixel and poor statistics enhances this.

Inherently, superior methods of image reconstruction are the so-called iterative methods in which the image is successively corrected to be consistent with the projection data to within desired error limits. These techniques involve iterative forward-projection and back-projection (between image and projections), and a number of different algorithms have been developed for the correction step at each iteration. Such methods have much more flexibility than filtered back-projection because models for the statistical nature of the data and the physical processes involved in data acquisition can be incorporated. For example, if the projection data are assumed to obey Poisson statistics, the likelihood of the reconstructed image can be maximized according to this, giving the so-called EM-ML (expectation maximization-maximum likelihood) algorithm. In contrast

to filtered back-projection, which produces a 'one-off' solution, iterative algorithms gradually converge to the desired solution, but the number of iterations needs to be carefully assessed to optimize the signal-to-noise ratio in the image and regional quantification of tracer.

Detection Efficiency and Noise

The efficiency of detection of annihilation photons obviously depends on the geometry of the tomograph and the ability of the detector material to absorb the photon energy (detector 'stopping power'). Considering a single ring of detectors of radius r and width (axial thickness) z , decreasing the radius increases the solid angle of detection (with r^2) but the detector volume decreases with r . Therefore overall efficiency increases with r . However, as r decreases, the solid angle for detection of random and scattered events increases, and clearly r must be large enough to provide the desired FOV (for head or body). In addition, spatial resolution worsens in the radial direction as r decreases. This implies that some compromise must be reached to balance these factors.

Although the 'raw' efficiency, or number of true coincidences acquired, is a basic determinant of the quality of a PET scanner, the complicating factors of scattered and random events and dead time have to be brought into the analysis. Details of the distribution of scattered events and correction methods can be found elsewhere, but for the present purposes it can be stated that scattered radiation (or 'scatter' for short) produces a relatively flat 'background' on the projection and image data, impairing contrast and reducing quantitative accuracy. The quantity of scatter detected, the scatter fraction (SF), is expressed simply in terms of the total true (unscattered + scattered) events (T_{tot}) and the scattered events (S) by

$$\text{SF} = S / T_{\text{tot}} \quad [5]$$

A similar reduction in contrast and quantification would result if random events were not subtracted from the data. As discussed above, subtraction of randoms is usually carried out 'on-line' during data acquisition and, although accurate quantitatively, imposes a statistical penalty on the net counts. If the numbers of prompt and random events are designated by P and R , then

$$T_{\text{tot}} = P - R \quad [6]$$

Assuming that Poisson statistics apply to these counts (e.g. the standard error of $P = \sqrt{P}$), the standard error of T_{tot} is

$$\sqrt{\left[(\sqrt{P})^2 + (\sqrt{R})^2\right]} = \sqrt{(P + R)} = \sqrt{(T_{\text{tot}} + 2R)} \quad [7]$$

Thus the standard error of T_{tot} is larger than $\sqrt{(T_{\text{tot}})}$ and increases with the rate of random events. Any procedure that reduces randoms, such as better shielding of extraneous

radiation or reduction in the coincidence time window (eqn [4]), will lower this uncertainty. The resultant standard error is conventionally described by the noise equivalent count (NEC) which is defined as follows. The fractional error of T_{tot} is $\sqrt{(T_{\text{tot}} + 2R)} / T_{\text{tot}}$. If a number (NEC) of hypothetical counts are collected (free of background), the fractional error is $(\sqrt{\text{NEC}}) / \text{NEC} = 1 / \sqrt{\text{NEC}}$. Equating this to the fractional error of T_{tot} gives

$$\text{NEC} = \frac{T_{\text{tot}}^2}{T_{\text{tot}} + 2R}$$

However, this expression is modified to take into account (a) the subtraction of scatter and (b) the fact that random events are spread fairly uniformly over the whole FOV of the PET tomograph, whereas unscattered true events are confined to the limits of the object. If the fraction of the FOV subtended by the object is f then the final expression for NEC is

$$\text{NEC} = \frac{[T_{\text{tot}}(1 - \text{SF})]^2}{T_{\text{tot}} + 2fR} \quad [8]$$

Another assumption implicit in this is that the subtraction of scattered events does not lead to an increase in noise. This would be so if, for example, a mathematical function were used to describe the distribution of scatter, but is not quite true in all methods.

NEC provides an overall factor for the determination of statistical quality, but it is of importance to investigate noise (statistical 'ripple') in the reconstructed image. As mentioned above in the discussion of reconstruction, image noise is greater than expected purely from the Poisson statistics of the projection data, owing to the filtering process. If there are an adequate number of projection angles and sampling points (LORs) per projection, then it can be shown that the noise/signal ratio (% root mean square) for a uniformly labelled object is given by

$$N/S(\%) = \frac{120\{N_{\text{re}}\}^{3/4}}{N^{1/2}} \quad [9]$$

where N is the total number of counts (trues) acquired and N_{re} is the number of 'resolution elements' contained within the object. The resolution element is defined as a region of dimensions (sampling distance)² or $(\Delta d)^2$. If the object is a disc (or a slice through a cylinder) of diameter 200 mm, the resolution FWHM = 6 mm and 10^6 counts are acquired, N/S is 19%. This is about 6 times what would be expected purely from Poisson statistics. Furthermore, if the resolution decreased to 3 mm FWHM, the number of counts N would have to increase by a factor of 8 to keep the N/S per resolution element constant. These simple calculations illustrate the importance of efficiency in PET. Resolution might be technically improved by using narrower detectors, but

the advantage will be lost if efficiency of detection is not increased. This point is of fundamental importance and is discussed more fully in the article on Instrumentation and Methods.

Introduction

The United States Federal Food and Drug Administration (FDA) regulations require the complete characterization of drug compounds. Since most pharmaceutical agents are organic compounds, much of this characterization involves various chromatography-based analytical techniques, as well as NMR, IR and various physical testing methods (such as DSC, TGA and XRD). The field of atomic spectroscopy has not traditionally played a major role in the characterization of pharmaceutical products, but on closer inspection it is clear that absorption and emission spectroscopic techniques can play a valuable role in the process of drug development and the quality of the product that finally reaches consumers.

From drug synthesis to quality control (QC) monitoring of over-the-counter medications, metals are found in all phases of the drug development process. Many metal-based products are used as imaging agents, and metals are used in the synthesis of drug substances, as excipients in tablets, capsules and liquids. In addition, trace metals can arise from the equipment used to manufacture a drug substance or compound. Because of the prevalence of metals associated with the drug development and manufacturing process, various atomic and emission-based techniques are often used to help fully characterize pharmaceutical products. The wide variety of pharmaceutical dosage forms and matrices, such as tablets, capsules, injectables, liquids, effervescent compounds, ointments and creams, makes the development of analytical methods and the analysis of samples a challenging and interesting process. In this article, we will describe the types of situations in the pharmaceutical industry where an analyst is likely to use atomic spectroscopy to solve an analytical problem and meet regulatory requirements. The pharmaceutical development process described will be based on the regulations and requirements in the USA.

Techniques of Interest in the Analysis of Pharmaceutical Products

The need for the determination of metallic constituents or impurities in pharmaceutical products has, historically, been addressed by ion chromatographic methods or

various wet-bench methods (e.g. the USP heavy metals test). As the popularity of atomic spectroscopy has increased, and the equipment has become more affordable, spectroscopy-based techniques have been routinely employed to solve analytical problems in the pharmaceutical industry. **Table 1** provides examples of metal determinations in pharmaceutical matrices, using spectroscopic techniques, and the reasons why these analyses are important. Flame atomic absorption spectrometry (FAAS), graphite furnace atomic absorption spectrometry (GFAAS), inductively coupled plasma-atomic emission spectroscopy (ICP-AES – also referred to as inductively coupled plasma-optical emission spectroscopy, or ICP-OES) and inductively coupled plasma-mass spectrometry (ICP-MS) are all routinely utilized in pharmaceutical applications. While there are other techniques of note available, such as microwave-induced plasma (MIP) or direct-coupled plasma (DCP), they have not been routinely used in the pharmaceutical industry, and will, therefore, not be discussed here. The theories involved in the use of FAAS, GFAAS, ICP and ICP-MS may be found in other articles of this Encyclopedia.

The first atomic spectroscopic techniques to see increased usage in the pharmaceutical field were FAAS and GFAAS of the current instrumental techniques available. They are among the most inexpensive, and have seen considerably more usage in all fields of endeavour, thus availing the pharmaceutical analyst of a vast array of knowledge upon which to draw and develop analytical methods. Because of the relatively low cost of the instrumentation, as well as its ease of use, QC laboratories in the pharmaceutical industry are more likely to have this type of atomic spectroscopy equipment than any other type. The speed and sensitivity of FAAS for elements such as Na, K and Li make it superior to wet-bench techniques. Examples of pharmaceutical products which require Na, K or Li determinations are nafcillin sodium (an antibiotic), oral solutions of potassium chloride (an electrolyte replenisher) and Lithane[®] (a psychotropic drug).

The speed of FAAS is, undeniably, a tremendous asset of the technique. Sample analysis time of less than 1 min per sample enables the analyst to process numerous samples in a given day by FAAS. FAAS is particularly useful when analysing a trace level analyte in the presence of another metal whose concentration is very high.

Table 1 Examples of metals that are determined in pharmaceutical analyses

<i>Element</i>	<i>Reason for assay/therapeutic area of use</i>	<i>Suggested analytical technique</i>
Ag	1. Determination of geographical origin of illicit drugs 2. Complex formation with drug for indirect determination (e.g. tetracycline) 3. Monitor Ag content of material (e.g. antiseptic creams, ophthalmic solutions)	1. Graphite furnace AA 2. ICP-AES 3. ICP-AES, graphite furnace AA
Al	1. Monitor Al in antihaemophilia preparations, which are sometimes precipitated with aluminium hydroxide 2. Determine geographical origin of illicit drugs 3. Monitor Al concentrations in dialysis solutions	1. Graphite furnace AA 2. Graphite furnace AA 3. ICP-AES
Au	1. Monitor Au concentration in arthritis drugs	1. ICP-AES
B	1. Monitor for presence of B in reagents used in synthesis 2. Monitor for leaching of B from glass vials, containers	1. ICP-AES, ICP-MS 2. ICP-AES, ICP-MS
Ba	1. Determination of geographical origin of material (e.g. illicit drugs) 2. Monitor Ba content in materials (e.g. used for diagnostic imaging)	1. ICP-MS 2. Flame AA, ICP-AES
Bi	1. Indirect determination of cocaine 2. Monitor Bi content in materials (e.g. antacid products)	1. ICP-AES 2. ICP-AES
Br	1. Determination of geographical origin of material (e.g. illicit drugs) 2. Monitor for presence of reagents used in synthesis, or as part of the compound	1. ICP-MS 2. ICP-MS
Ca	1. Determination of Ca in calcium supplements and vitamins 2. Monitor Ca impurities in magnesium oxide (often used as an excipient in pharmaceutical preparations) 3. Determination of geographical origin of material (e.g. illicit drugs)	1. ICP-AES, graphite furnace AA 2. Flame AA 3. ICP-MS
Cd	1. Monitor Cd in dialysis solutions 2. Monitor heavy metals content of medicinal plants or herbal drugs 3. Determination of geographical origin of material (e.g. illicit drugs) 4. Monitor trace metals content in materials (e.g. penicillin G)	1. Graphite furnace AA 2. Graphite furnace AA, flame AA 3. ICP-MS 4. ICP-AES
Co	1. Complexing agent for indirect determination of drug (e.g. salicylic acid, lidocaine) 2. Monitor Co in dialysis solutions 3. Monitoring trace metals content in materials (e.g. penicillin G) 4. Determination of B-vitamins	1. Flame AA 2. Graphite furnace AA 3. ICP-AES 4. HPLC-FAAS
Cr	1. Complexing agent for indirect determination of drug (e.g. thioridazine, amitriptyline, imipramine, orphenadrine) 2. Determine geographic area of origin of illicit drugs 3. Monitor trace metals content in materials (e.g. penicillin G) 4. Monitor Cr content in vitamins	1. Flame AA 2. Graphite furnace AA 3. ICP-AES 4. Graphite furnace AA
Cs	1. Monitor for presence of reagents used in synthesis	1. Flame AA
Cu	1. Complexing agent for indirect determination of drug (e.g. lincomycin, isonicotinic acid hydrazide, ethambutol hydrochloride, neomycin, streptomycin) 2. Monitor Cu in dialysis solutions 3. Monitor heavy metals content in medicinal plants 4. Determine Cu concentrations in vitamins 5. Monitor Cu in herbal drugs 6. Monitor trace metals content in materials (e.g. penicillin G) 7. Determination of synthetic route and geographical origin of material (e.g. illicit drugs or to prevent patent infringement)	1. Flame AA 2. Flame AA, graphite furnace AA 3. Graphite furnace AA 4. ICP-AES 5. Flame AA 6. ICP-AES 7. ICP-MS
Fe	1. Monitor Fe in dialysis solutions 2. Monitor Fe contamination in magnesium oxide (often used as excipient in pharmaceutical preparations) 3. Monitor Fe concentrations in vitamins 4. Determination of geographical origin of illicit drugs 5. Determination of trace metals content of materials (e.g. penicillin G) 6. Monitor Fe concentrations in imaging agents	1. Flame AA 2. Flame AA 3. ICP-AES 4. ICP-MS 5. ICP-AES 6. ICP-AES, flame AA
Gd	1. Monitor Gd content in imaging agents (e.g. Prohance®)	1. ICP-AES
Hg	1. Monitor Hg content of materials (e.g. antiseptic solutions and creams, ophthalmic solutions) 2. Monitor heavy metals content of materials	1. Flame AA 2. ICP-MS

(Continued)

Table 1 Continued

<i>Element</i>	<i>Reason for assay/therapeutic area of use</i>	<i>Suggested analytical technique</i>
I	1. Determination of geographical origin of illicit drugs	1. ICP-MS
In	1. Monitor trace metals concentration in final drug substance	1. ICP-MS
K	1. Monitor for presence of reagents used in synthesis	1. Flame AA
	2. Monitor salt counter-ion concentration	2. Flame AA, ICP
Li	1. Monitor for presence of reagents used in synthesis	1. Flame AA, ICP-MS
	2. Monitor Li concentration in drug (e.g. lithium-based psychotropic drugs for treatment of manic/depressive disorder)	2. Flame AA
Mg	1. Determine Mg concentrations in vitamins	1. ICP-AES
	2. Determination of geographical origin of illicit drugs	2. ICP-MS
	3. Monitoring magnesium stearate content or magnesium oxide (used as lubricant, sorbent, respectively, in pharmaceuticals)	3. ICP-AES, flame AA
Mn	1. Determination of geographical origin of illicit drugs	1. Graphite furnace AA
	2. Monitor trace metals content of materials (e.g. penicillin G)	2. ICP-AES, ICP-MS
Mo	1. Monitor trace metals content of materials (e.g. penicillin G)	1. ICP-AES
Na	1. Determination of synthetic route and geographical origin of material (e.g. to prevent patent infringement; illicit drugs)	1. Flame AA, ICP-MS
	2. Monitor salt counter-ion concentration of salt content (e.g. in diagnostic agents, in electrolyte replenishing solutions, in cathartics)	2. Flame AA, ICP-AES
Ni	1. Monitor Ni in dialysis solutions	1. Graphite furnace AA
	2. Determination of geographical origin of illicit drugs	2. Graphite furnace AA
	3. Monitor trace metals content of materials (e.g. penicillin G)	3. ICP-AES, ICP-MS, graphite furnace AA
P	1. Determine P concentration of vitamins	1. ICP-AES
	2. Determination of geographical origin of illicit drugs	2. ICP-MS
	3. Determination of constituents of materials (e.g. alendronate sodium)	3. ICP-AES
Pb	1. Determination of Pb in calcium supplements	1. ICP-AES, graphite furnace AA
	2. Monitor Pb in dialysis solutions	2. Flame AA
	3. Monitor heavy metals content in medicinal plants	3. Graphite furnace AA
	4. Determination of geographical origin of illicit drugs	4. ICP-MS
	5. Monitor trace metals content of materials (e.g. penicillin G)	5. ICP-AES
Pd	1. Determination of residual catalyst in pharmaceuticals (e.g. fosinopril, semisynthetic penicillin)	1. ICP-MS, graphite furnace AA
	2. Determination of geographical origin of illicit drugs	2. ICP-MS
Pt	1. Speciation of Pt-containing compounds (cisplatin, transplatin, carboplatin, JM-216)	1. HPLC-ICP-MS, graphite furnace AA
	2. Monitor for residual catalysts	2. ICP-MS, graphite furnace AA
Rh	1. Monitor for residual catalysts used in synthesis of pharmaceuticals	1. ICP-MS
Sb	1. Determination of synthetic route or geographical origin of material (e.g. for illicit drugs, or to prevent patent infringement)	1. ICP-MS
	2. Monitor Sb content in materials (e.g. final drug substances)	2. ICP-MS
Se	1. Monitor for presence of reagents used in synthesis	1. Graphite furnace AA, ICP-MS
	2. Monitor Se concentration in vitamins	2. Graphite furnace AA, ICP-MS
	3. Monitor Se concentration in anti-fungal and anti-seborrhoeic products	3. Graphite furnace AA, ICP-MS
Si	1. Determination of geographical origin of illicit drugs	1. ICP-MS
	2. Monitor for Si contamination from silicone-based compounds used in packaging processes	2. ICP-MS, ICP-AES
	3. Monitor for silica gel (used to prevent caking or as a suspending agent)	3. ICP-AES
Sn	1. Monitor for presence of reagents used in synthesis	1. Graphite furnace AA, ICP-MS
	2. Monitor heavy metals content of materials	2. Graphite furnace AA, ICP-MS
Sr	1. Determination of geographical origin of illicit drugs	1. Graphite furnace AA, ICP-MS
Ti	1. Determine Ti concentration in sunscreens (titanium dioxide is often used in sunscreens)	1. Flame AA
	2. Monitor trace metals content of materials (e.g. penicillin G)	2. ICP-AES

	3. Determination of geographical origin and synthetic route of material (e.g. illicit drugs or to prevent patent infringement)	3. ICP-MS
	4. Monitor trace metals content of materials (e.g. penicillin G)	4. ICP-AES
	5. Monitor Zn content of materials (e.g. insulin, antibiotics, sunscreens)	5. ICP-AES, flame AA

This situation is encountered when analysing products which incorporate a metal into the drug substance, such as Platinol[®] (an oncology agent), Prohance[®] (an imaging agent) and Myochrysine[®] (a product used for the treatment of rheumatoid arthritis). These products contain high concentrations of platinum, gadolinium and gold, respectively. These elements have very rich spectra, with numerous spectral lines, which may overlap with the spectral lines of the analyte elements. In such cases, FAAS is a better choice for trace metals determination than ICP-AES, since coincident line overlap is not a problem with the former technique, but presents a considerable problem for the latter.

GFAAS is also commonly found in pharmaceutical company laboratories, owing to the affordability of this spectroscopic instrumentation. GFAAS is ideally suited for the analysis of samples which are available only in small quantity, because it requires considerably less sample for a given analysis than FAAS or any of the plasma-based techniques (e.g. 20 μ L per determination versus 3 mL per determination). Additionally, GFAAS has the ability to remove the sample matrix before atomization of the sample for analyte determination, thus affording the analyst great versatility in the analysis of samples which are composed of rich organic matrices. As with FAAS, GFAAS is also well suited to those pharmaceutical applications where a low-concentration analyte is determined in the presence of a high-concentration metal.

Second in popularity to atomic absorption-based techniques for applications in the pharmaceutical industry is ICP-AES. This instrumentation affords the analyst greater flexibility, with a wider dynamic range and a broader range of elements which can be analysed in a single run. It is often employed to simultaneously determine elements such as Al, Cr, Fe, Mn, Ni, Zn, P, B, Pd and Pt in pharmaceutical matrices. Although FAAS and GFAAS may also be used to monitor these elements, ICP-AES can scan all of these elements in a single analysis (either by scanning or by the use of a simultaneous unit). In addition, ICP-AES can monitor multiple wavelengths for each element for confirmation of its presence, making it an attractive alternative to either FAAS or GFAAS. The wide linear range of ICP-AES is

quite useful in the analysis of pharmaceutical samples, owing to the time saved in developing methods. In addition, the need to make multiple dilutions of a sample is eliminated, as is the need to run multiple standard concentrations within an analysis.

Depending on the stage of development of a pharmaceutical product, the decision for selecting ICP-AES over an AAS technique may simply be the amount of sample available for a set of analyses. The advent of axial ICP-AES systems, with their increased sensitivity, makes ICP-AES an excellent choice where large amounts of sample are not available. The axial ICP-AES system allows the analyst to use considerably less sample than in the past, while achieving the same detection limits and minimum quantifiable limits.

Owing to its ability to monitor multiple wavelengths for a given analyte, and its wide linear range, ICP-AES is well suited for identity testing. An identity test is one in which the analyst is only confirming or denying the presence of a given analyte. In some cases, a compound may have a sufficiently high concentration of a given metal, making it possible to monitor the metal to determine if the compound is authentic. Monitoring of multiple wavelengths is often used to positively confirm the identity of the analyte metal, thus fulfilling the needs of an identity test.

ICP is seeing more use as a sample introduction system for various hyphenated techniques. A more recently utilized technique for the pharmaceutical industry is inductively coupled plasma-mass spectrometry (ICP-MS). ICP-MS offers excellent versatility and sensitivity to the analyst, and greatly complements any pharmaceutical atomic spectroscopy laboratory. The sensitivity of the technique and its scanning capabilities make it an ideal choice for the analysis of pharmaceuticals in the early stages of development, when sample material may be in extremely short supply, as the chemists try to optimize and change the synthesis. ICP-MS has been used in our laboratories as an alternative to the United States Pharmacopeia (USP) heavy metals test, providing more accurate, element-specific results for several very toxic metals. The USP test requires a minimum of 1 g of material to perform the nonspecific sulfate ashing procedure. In comparison, the ICP-MS procedure requires

only 25 mg and provides element-specific information on 14 different metals. Additionally, ICP-MS is able to examine different isotopes of a given metal present in a sample. This can be quite useful when studying imaging agents, which may be formulated with radioisotopes as part of the desired active ingredient. ICP-MS is very useful in the analysis of trace metals in a matrix containing another metal at high concentrations. As noted earlier, coincident lines may cause problems for ICP-AES determinations in these cases, and the sensitivity or need for individual lamps may slow or preclude the use of FAAS or GFAAS for these determinations as well. With ICP-MS, the high-concentration metal may be 'skipped', while several analyte metals present at trace concentrations may be examined in a single analysis.

All of the techniques discussed have been used to analyse pharmaceutical products which have no chromophores and cannot be analysed by traditional UV-based chromatographic systems. In these cases, metallic complexes are formed with the compounds of interest and then indirectly determined by FAAS, GFAAS, ICP-AES or ICP-MS analysis. This approach can provide valuable information in a short time, one of the chief advantages of spectroscopic techniques when compared with a chromatographic technique, which may take several minutes to an hour per sample analysis. In addition to the situations where a pharmaceutical product is complexed with a metal before analysis by these techniques, FAAS, ICP-AES and ICP-MS are also used in concert with various chromatographic techniques, such as LC-ICP-AES, LC-ICP-MS, LC-ICP-AES, LC-ICP-MS, LC-FAAS and LC-FAAS. The coupling of chromatographic systems with FAAS, ICP-AES and ICP-MS instruments has provided the pharmaceutical analyst with tools which can be used to speciate metallic constituents in drug products, to achieve even lower detection limits, and to examine the different isotopes of metallic constituents present in a sample. Indeed, the sensitivity, flexibility and speed of each of these techniques prove to be valuable in the pharmaceutical industry.

The plasma-based techniques can also serve as detectors for laser ablation (LA) and electrothermal vaporization (ETV). These techniques are well-suited for the analysis of solid samples. ETV can also be used to analyse liquid and slurry samples. Both techniques use small quantities of material and, when interfaced with ICP-MS, are quite sensitive. A cool plasma accessory can also be interfaced with the ICP-MS. This allows for the removal or minimization of interferences caused by the formation of molecular species in the plasma, permitting the determination of Li, Na, Ca, K, Fe and Cr which cannot be analysed successfully by conventional ICP-MS. Such analyses exhibit the same sensitivity as afforded by FAAS.

How Is an Analytical Technique Selected in a Pharmaceutical Laboratory?

The Stages of the Drug Development Process – Some Background

The role that atomic spectroscopy plays in the pharmaceutical industry may be directly linked to the various stages of the drug development process. To understand how these techniques might be encountered, it is important to examine, in closer detail, what happens during each step of the drug development process.

From the time a potential new drug candidate is identified to the time that it reaches the market, it undergoes considerable testing and evaluation. It is imperative that the testing and evaluation of a new drug candidate be completed as quickly as possible, since the pharmaceutical company's patent on a drug has a finite life. The patent gives the pharmaceutical company exclusive rights to the production and sale of the drug once it is approved by the FDA. Once the drug goes off patent, other pharmaceutical companies are allowed to produce a generic form of the drug. The sale of these generic forms can have a great impact on the sales of the originator company product. One of the goals of drug development is to maximize the length of time in which the company has exclusive marketing rights. It is not uncommon for the sales of a major pharmaceutical product to exceed \$1 billion a year at the time the exclusivity period expires. This translates to ~\$100 million per month or more. Thus, each month the company can reduce from the development cycle can literally be worth hundreds of millions of dollars.

SmithKline-Beecham's product, Tagamet[®], illustrates this well. The earnings from the sale of Tagamet[®] were £484 million in 1994 (last year of exclusivity). The earnings in 1995, the first full year Tagamet[®] was off patent, were £286 million, a drop of almost 41%. Therefore, it is beneficial to the company to reduce the time and expense required to get a drug product through the discovery and development phases to market. The steps and the goals of each phase in the development process are quite specific and well defined by the FDA, and are summarized in **Table 2**.

Preclinical (Discovery) Testing

The earliest stage of drug development is the preclinical or discovery phase. During this phase, a potential drug candidate is identified, and work begins on developing an optimal synthesis. Preliminary assessments are made regarding the safety and biological activity of the potential drug candidate in laboratory and animal studies. At this stage of development, the synthetic chemist has very little experience with the molecule and may utilize exotic catalysts to produce the first few grams of the materials.

Table 2 The phases of the drug development process

<i>Step in the drug development process</i>	<i>Goal/objective of the step in the process</i>
Preclinical (discovery) phase	Assess the drug's safety and biological activity in the laboratory and animal studies
Phase I clinical trials (IND phase)	Establish the safety and bioavailability of the compound in humans. This is typically done in studies using healthy volunteers
Phase II clinical trials (IND phase)	Determine proof-of-principle for the drug's mode of action. Monitor for any possible side effects and evaluate the drug's effectiveness. This study uses patient volunteers who have the disease/condition for which the drug is targeted
Phase III clinical trials (IND phase)	Establish dose form and dosage strength for registrational filing. Continue to monitor possible side effects and adverse reactions. Verify the effectiveness of the drug in the targeted patient population. This study involves many more patient volunteers than the Phase II study
FDA review/approval process	The FDA reviews the new drug application (NDA). If it is fully approved, the drug may proceed to market. If the NDA is not fully approved, the FDA may require additional testing, answers to questions or it may reject the application

Analyses of preliminary batches of the drug candidate and key intermediates are performed to ensure the preliminary safety data is reflective of the drug candidate and not impurities generated by the synthetic process. Since patents have finite lifetimes, time is of the essence, especially at this early stage, when the drug has not yet been evaluated in man. During this phase of development, the salt and/or crystal form of the drug substance may not have been selected. As a result, samples analysed can vary in solubility properties, pH, purity, etc. Analyses that are typically performed include counterion, trace metals (from equipment sources, e.g. stainless steel) and trace catalyst determinations.

The flow chart given in **Figure 1** illustrates the thought processes involved in the selection of a given analytical technique for the determination of metals in pharmaceutical-related samples.

The atomic spectroscopist is typically involved in supporting a new potential drug candidate before the final salt and/or crystal form have been selected. Several forms of the drug substance (salt forms, and/or polymorphs) are considered during the discovery phase and are generated in small laboratory batches via several synthetic pathways or crystallization procedures. The atomic spectroscopy laboratory plays an important role in the selection of the final form by assaying these samples for trace metals, salt counter-ions and trace catalysts used in the syntheses. Once a final form has been selected, testing continues to support the optimization of the synthetic process.

The selection of an appropriate analytical technique is highly dependent upon the time constraints that pharmaceutical companies set for the complete development of a drug product. As the costs of developing drugs have risen, the push within the pharmaceutical industry has been to reduce the time from discovery to the clinical studies as much as possible. This is driven by the fact that somewhere between one in seven and one in ten potential drug candidates in development actually

make it to market. Therefore, results on preclinical samples are usually required in a short time (a few days, or hours) so that refinements to the synthetic process can be made, if necessary. The technique that is chosen for the assay must be rapid, meet the sensitivity requirements and generally consume small quantities of material. To expedite the analysis, it is prudent to perform as many determinations as possible in one assay. ICP-AES and ICP-MS are well suited for this type of determination; however, they are not ideal for all trace metals. The elements Na and K must be analysed by FAAS unless they are present at concentrations high enough for ICP-AES.

Once the final form has been selected and the synthesis refined, methods are developed and validated for metals that are present in reagents used in the synthesis, metals that may arise from the equipment used in the synthesis and metals that are incorporated into the active ingredient in the final drug product. Validated methods are often required for synthetic intermediates as well. In addition, the FDA requires that a method be validated for the determination of heavy metals (i.e. lead, mercury, etc.) in the final drug substance. The USP heavy metals test requires one gram of sample for each determination. This method is non-specific and is based on a sulfate ashing of the sample, followed by a colorimetric comparison with a lead solution standard. Since this much material is usually not available in this phase of drug development, ICP-MS has been demonstrated to be an excellent technique for the determination of heavy metals in early development drug candidates. ICP-MS offers element-specific information and utilizes substantially less sample.

In addition to support of the drug substance, analyses are performed on starting materials and any raw materials used in the last step of the synthesis. Small batches of the drug substance which will be used in animal toxicology and pharmacokinetic studies must also be analysed. Once a synthetic process and final form have been

Figure 1 Flow chart of method development decision-making process. Reproduced with permission of the editor from *Atomic Spectroscopy: Pharmaceutical Applications of Atomic Spectroscopy* 12(9): 14–23 (1997) published by Advanstar Communications.

selected, an investigational new drug (IND) application is filed with the FDA.

Clinical (IND) Phase

The IND contains information regarding the drug's composition and synthesis and lists all specifications that have been set for the drug substance. Specifications are set for many tests, which may include trace metals. All subsequent batches of the drug that will be used in clinical studies must meet these specifications before their release. The IND contains information regarding animal toxicology study data and protocols for clinical trials. The IND clinical study protocol for a new drug candidate consists of three clinical phases (**Table 2**).

Optimization and refinement of the synthetic process continues during the IND phase. The synthetic chemists scale up the synthesis to produce kilogram size batches. Support of this stage of drug development is similar to that performed to support synthesis optimization on small laboratory batches during the preclinical phase. Validated methods must be refined as the synthesis is refined, because even the slightest change in the synthesis can have a profound effect on whether a previously validated method will continue to be adequate for the

trace metal determination. The use of a different solvent or reagent can be sufficient to invalidate a method.

During the preclinical stage of drug development, speed and sample consumption are typically the most important factors when selecting a technique; however, as the compound moves through the clinical phase of development there are other factors to consider. First, the atomic spectroscopist must consider the analytes of interest and the sensitivity that is required. Speed is still an important issue; however, sample consumption is less of a critical factor, since batch sizes of several hundred grams to several kilograms are routinely being produced. One must consider whether the method will be transferred to a QC laboratory since the instrumentation within such a laboratory will often dictate which spectroscopic technique is used. If a QC laboratory will be performing the analysis, then usually either FAAS or GFAAS will be preferred since this instrumentation is typically found in QC laboratories, owing to the lower cost, compared with plasma-based instrumentation. This poses a challenge when one requires the sensitivity of GFAAS but must dissolve the drug substance in an organic solvent that is too viscous for GFAAS systems to handle. ICP-AES or ICP-MS would be the ideal alternative, but most QC laboratories cannot afford such instrumentation.

Once the development of the drug candidate passes into the clinical Phase II and III studies, the demand for bulk substance increases. The synthesis is scaled up in the pilot plant to batch sizes ranging from ten to several hundred kilograms, and eventually to final production size batches of the final drug substance. The atomic spectroscopist will sometimes be called upon to help troubleshoot the process during the scale-up. Troubleshooting samples come in a variety of forms: discoloured drug substance or intermediate; scrapings from the equipment used in the synthesis; reagents used in the synthesis; filters used in the synthesis; liquid streams from the processing or slurries that were produced owing to a malfunctioning of the equipment. Sometimes the chemist will have an idea as to why the process failed and can help narrow down the investigation for the analyst. The cause of a process excursion can range from the use of a reagent contaminated with metals to equipment failure, such as a lubrication oil or coolant leak or the corrosion of the stainless steel equipment by the reaction by-products. ICP-MS is an excellent tool for assessing the problem quickly by performing qualitative or semi-quantitative scans of the periodic table. If these scans indicate that any metals are present at concentrations high enough for concern (several parts per million), alternative techniques, such as ICP-AES or FAAS, are used to confirm and quantitate their presence in the sample. Usually, but not always, sample consumption is not of great concern, but the speed of the technique is critical, since the chemist cannot proceed with the processing of the batch(es) until the source of the problem is identified. In analysing oils, contaminated filters, discoloured drug substance or intermediates, the analyst will often focus on the possible presence of wear metals from lubricating oils (Al, Cr, Cu, Fe, Pb, Sn and Mo), metals from coolant contamination (Na, K and B) and metals found in stainless steel (Ni, Cd, Pb, Al, Fe, Cr, Cu, Mn and Zn). ICP-AES is sensitive enough for most of these metals and, because it is capable of multielement analyses, it is also rapid enough to satisfy the short turn-around times required for processing these samples. Na and K must be assayed by FAAS unless they are present at high enough concentrations for ICP-AES.

LA-ICP-MS can be used to quickly analyse solid samples, such as filters or scrapings from the equipment. A minute amount of sample is consumed and analysis is fast, as no sample preparation is required. LA-ICP-MS is especially useful when analysing solid samples with distinct discolourations, since the laser can be focused on the area of interest to increase sensitivity. Each discoloured area can be ablated and assayed separately to determine its metallic composition. Often, these areas are caused by contamination from an oil or coolant that has leaked from the equipment. This affords the spectroscopist great selectivity over a conventional dilute-

and-shoot method in which the small discoloured areas cannot be analysed separately.

Before the introduction of cool plasma ICP-MS, qualitative ICP-MS scans did not provide accurate information on Li, Na, K, Ca, Cr and Fe (owing to spectral interferences or the element being easily ionized). Therefore, ICP-AES or FAAS assays were required for accurate information on these elements. The advent of cool plasma ICP-MS makes it possible to quickly analyse all metals using only one spectroscopic technique, which is important when only a small amount of sample is available.

NDA Phase (Phase IV)

In the final stage of drug development, a new drug application (NDA) is filed with the FDA. Animal and clinical studies continue during the NDA phase. Stability tests of the drug substance and product continue, including studies of the commercial formulation in the market packaging. The spectroscopy laboratory supports this stage of development by performing analyses that are included in the specifications that have been set for the drug substance and product, using the methods filed with the NDA. The spectroscopist may see samples during this phase that are generated when the manufacturing process of the drug substance or product is transferred to a new production facility. The steps that are taken in

Table 3 Examples of pharmaceutical compounds which contain metals

<i>Metal</i>	<i>Examples of uses in pharmaceutical compounds</i>
Na, Mg, Ca, K	Used in various excipients, in vitamins, in dialysis solutions and Eye Stream [®] , a liquid used for irrigating eyes, contains Na, Mg and K
Pt	Used in several oncology drugs: Paraplatin [®] , Platinol [®] and Cisplatin [®]
Zn	Used in Insulin and in Cortisporin [®] ointment (a steroid-antibiotic ointment)
Li	Used in Lithobid [®] and Cibalith-S [®] , both of which are used for the treatment of manic-depressive psychosis
Al	Often used in antacid preparations, such as AlternaGel [™] or Mylanta [®]
Ag	Used as a topical antimicrobial for the treatment of burns in Silvadene [®] cream, 1%
Au and Na	Used in Myochrysine [®] injection, for the treatment of rheumatoid arthritis
Fe	Active ingredient in Chromagen [®] , a drug used in the treatment of anaemia. Also, sometimes used in pigments for printing tablets or capsules
Se	Selsun Blue [®] , a dandruff shampoo
Mn	Active ingredient in LumenHance [®] , an imaging agent

selecting and using a spectroscopic technique are the same as those described in the previous section.

The last stage in this phase consists of FDA inspections and a review of the NDA. During these inspections, the auditors may examine instrument calibration records and previous batch results to ensure that they were collected under Good Laboratory Practices (GLP) and/or Good Manufacturing Practices (GMP). Based on the inspection, the FDA will either approve the new drug candidate, require additional testing, request answers to questions and concerns they have or reject the drug product. Some examples of pharmaceutical compounds that contain metals are given in **Table 3**.

The role that the atomic spectroscopy laboratory plays in the drug development process is an important one. It helps ensure the safety and quality of the drug products that are approved by the FDA.

Introduction

In conventional absorption spectroscopy the measurement of absorption is transferred to a measurement of the radiation power transmitted through the sample. On the contrary, in photoacoustic spectroscopy, the absorbed power is determined directly via its heat and hence the sound produced in the sample. Photoacoustics, also known as optoacoustics, was pioneered by AG Bell, in 1880. The photoacoustic (PA) effect concerns the transformation of modulated or pulsed radiation energy, represented by photons, into sound. In general, two aspects have to be considered: first, the heat production in the sample by the absorption of radiation; and second, the resulting generation of acoustic waves. Closely related to the PA effect are photothermal (PT) phenomena which are caused by the original heating via absorption of radiation. While the PA effect is detected via acoustic sensors such as microphones, hydrophones or piezoelectric devices, the PT phenomena are sensed via the induced changes of the refractive index of the media by probe beam deflection, thermal lensing or, also, PT radiometry. Both PA and PT spectroscopy are widely used today in many applications. Experimental aspects are outlined in a separate article while this article discusses the main characteristics of this spectroscopic tool. The great potential is illustrated with examples from applications on solids, liquids and gases as well as in life sciences.

Spectroscopic Applications

PA and PT phenomena are widely used for numerous non-spectroscopic applications such as the determination of thermal diffusivity, non-destructive testing of materials (in particular the probing of sub-surface defects) by thermal wave imaging, time-resolved studies of de-excitation processes or on biological photoreceptors, studies of phase transitions, etc. Here, only spectroscopic applications are considered that demonstrate the main characteristics and the potential of photoacoustic spectroscopy (PAS). In the following, illustrative examples are presented for solids, liquids, gases, biological and medical samples.

Studies on Solids

A main advantage of PAS applied to solids is the fact that no elaborate sample preparation is required and unpolished

sample surfaces pose no problems. Since the PA signal is proportional to the *absorbed* energy, even spectra of strongly scattering samples, e.g. powders, can easily be measured. However, it should be mentioned that owing to the complex nature of the signal generation involving interstitial gas expansion, etc., PA studies on powders are usually only qualitative. Another advantage is the high sensitivity that is achieved because the PA detection is a null method for measuring absorption. Hence, absorbances as low as 10^{-7} can be detected. For modulated radiation a simple theoretical model has been developed which is based on the fact that the acoustic signal is due to a periodic heat flow from the solid to the surrounding gas, as the solid is cyclically heated by the absorption of the chopped light. Six different cases are distinguished, depending on the optical and thermal properties of the solid samples. This allows the unique feature of measuring totally opaque materials which is impossible by conventional transmission measurements. Hence PAS is a technique to study weak bulk and surface absorption in crystals and semiconductors, to evaluate the level of absorbed energy in thin films, to measure the spectra of oxide films in metals, various powders, organic materials, etc. and also to investigate multi-layered samples.

An early example is shown in **Figure 1** for the insulator Cr_2O_3 . Spectrum (A) depicts the normalized PA spectrum of Cr_2O_3 powder in the 200 to 1000 nm region. In comparison spectrum (B) shows an optical absorption spectrum obtained on a $4.4\text{ }\mu\text{m}$ thick bulk crystal, taken parallel and vertical to the crystal c -axis, whereas spectrum (C) represents a diffuse reflection spectrum of Cr_2O_3 powder. The advantage of PAS is obvious in that the two crystal-field bands of the Cr^{3+} ion at 460 and 600 nm are almost as clearly resolved in the PA spectrum of the powder as they are in the crystal spectrum, and substantially better resolved than in the diffuse reflectance spectrum. It should be noted, however, that the theoretical description of the PA effect in strongly scattering media is not straightforward and quantitative data are therefore difficult to determine from such spectra.

Another example concerns adsorbates on the surfaces of solids. PAS is expected to be rather sensitive to surface adsorption, especially if the substrate is transparent or highly reflective in the wavelength region in which the adsorbate absorbs. Both sinusoidal modulation of the incident laser beam and pulsed lasers have been used for this purpose. An interesting version is the modulation of the

Figure 1 (a) Normalized PA spectrum of Cr_2O_3 powder, (b) optical transmission spectrum of a $4.4\text{ }\mu\text{m}$ thick Cr_2O_3 crystal, (c) diffuse reflectance spectrum of Cr_2O_3 powder. laser beam polarization to suppress the background signal that originates from substrate absorption. A fraction of only 0.005 of a monolayer of ammonia (NH_3) adsorbed on a cold silver substrate in ultrahigh vacuum was detected. An example is shown in **Figure 2** where the PT signal is recorded as a function of time as ammonia is slowly admitted to the system and condenses on the silver substrate. The signal of a microbalance as indicator of molecular coverage is monitored simultaneously. Later studies were aimed at investigating the kind of adsorption in more detail, e.g. to differentiate between chemisorption and physisorption, by combining the high spectral resolution and high sensitivity offered by pulsed laser PAS.

In other studies, the wide free spectral range offered by Fourier transform infrared (FTIR) spectroscopy combined with the step-scan methods has been increasingly applied in conjunction with PA detection for infrared spectral depth profiling of laminar and otherwise optically heterogeneous materials. IR spectra that are often unavailable by use of other techniques become accessible from

Figure 2 Photothermal signal and microbalance record versus exposure time as ammonia molecules are slowly adsorbed on a silver substrate. The maximum coverage is 0.8 monolayers, the ammonia partial pressure in the system is 8×10^{-9} Torr. The noise level (left) indicates the signal from the clean substrate. samples that are strongly absorbing or even opaque, from strongly light-scattering samples and from samples *in situ*. The scheme is also applied as an analytical tool for chemical characterization and quantification, e.g. of polychlorinated biphenyls (PCBs) in industrial waste management such as PCB contamination of soils.

Finally, the available spectral range for PA studies on solids has been extended to the X-ray region by using hard X-rays from synchrotron radiation. As an example, the X-ray absorption near Cu K-edge regions has been measured on copper (Cu), Cu alloys (brass) and Cu compounds (CuO , Cu_2O and CuInSe_2) with a PA detector and compared with the usual X-ray absorption ($10\text{ }\mu\text{m}$ thick Cu and brass foils and $<50\text{ }\mu\text{m}$ thick powdered samples of CuO , Cu_2O and CuInSe_2 put on Scotch tape were used as specimens). It was found that the energy peak values derived from the PA spectra agree with those deduced from optical density spectra, suggesting that the heat production processes are also reflected in the absorption spectra. A more detailed insight is obtained by dividing the PAS data by the optical density data, i.e. by forming the ratios $\text{PAS}:\log(I_0/I)$, which are proportional to the heat production efficiency. In **Figure 3** these ratios are plotted for Cu, Cu_2O and CuInSe_2 versus the photon energy near the K-edge of Cu. The results clearly indicate differences between X-ray absorption and PA spectra and hence imply a spectral variation of the heat production efficiency.

Figure 3 X-ray PA spectra normalized with optical transmission spectra ($\text{PAS:log } [I_0/I_1]$), where I_0 and I_1 denote the incident and transmitted intensity, respectively, at the K-edge region for different copper compounds. (a) Pure Cu, (b) Cu_2O and (c) CuInSe_2 . Obviously, the heat production process is also different in Cu_2O compared with the other Cu compounds.

Studies on Liquids

Experimental and theoretical PA and PT studies on liquids comprise a wide absorption range from 'transparent' to opaque liquids.

For investigations on weakly absorbing media a flash-lamp-pumped dye laser with pulse energies of 1 mJ was used as excitation source and a submersed piezoelectric transducer for detecting the generated acoustic signals. The high sensitivity permits, e.g. the recording of the water spectrum in the visible range where accuracies of other techniques such as long-path absorption measurements are often limited. Another example concerns the study of weak overtones of the C–H stretch absorption band of hydrocarbons up to the 8th harmonic. In **Figure 4** the absorption band of the 6th harmonic at 607 nm of benzene dissolved in CCl_4 is plotted for different dilution ratios of benzene. With increasing dilution, the absorption peak is obviously blue-shifted and both the line width and the line asymmetry decrease. These and other results

Figure 4 PA spectra of the 6th harmonic absorption of the C–H bond of benzene dissolved in carbon tetrachloride (CCl_4) in arbitrary linear units, as the volume dilution ratios indicate. demonstrate that PAS permits the measurement of minimum absorption coefficients of 10^{-6} cm^{-1} , corresponding to absorbed laser pulse energies of only 1 nJ.

Another field of interest concerns analytical investigations on pollutants in liquids. Detection limits in the sub-ppb range were achieved by PAS, e.g. for carotene or cadmium in chloroform or for pyrene in heptane. More recently, pesticides in aqueous solutions have attracted interest. Different experimental arrangements with pulsed or CW pump lasers and various PA and PT lens detection schemes were used in these studies. Limits of detection are down to below 10^{-6} cm^{-1} , corresponding to ppb concentrations. An example is presented in **Figure 5** where the calibration curves for the detection of the dinitrophenol herbicide DNOC in aqueous solutions are compared with the untreated standard solution. The techniques used involved PT techniques, namely PT deflection spectroscopy (PDS, **Figure 5a**), thermal lensing (TL, **Figure 5b**), PT interferometric spectroscopy (PIS, **Figure 5c**), PAS (**Figure 5d**) and a conventional spectrophotometer (Cary 2400, **Figure 5e**). Obviously, the detection limit of the spectrophotometer in the low ppb ($\mu\text{g kg}^{-1}$) range is exceeded by the PA and PT methods. In particular, TL and PDS appear superior in the determination of environmental pollutants. It should be noted that both US and EU standards require detection limits of $0.1 \mu\text{g l}^{-1}$ for pesticides in drinking water.

On the other end of the scale are opaque or strongly absorbing liquids. PA spectroscopy has the advantage that it can easily determine absorption coefficients that are two to three orders of magnitude higher than accessible by conventional transmission spectroscopy. Various schemes have been proposed for this case including the optothermal window. As example, the *trans*-fatty acid (TFA) content of margarine was determined using a CO_2 laser and the optothermal window. Good agreement with alternative techniques such as FTIR, gas–liquid chromatography and thin-layer chromatography was obtained.

Studies on Gases

Early PAS studies on gases had already demonstrated the high sensitivity that is achieved with a rather simple setup and have subsequently favoured further developments in trace gas monitoring. In comparison with conventional optical absorption measurements, PAS offers the following main advantages: (i) only short pathlengths are required which enables measurements at wavelengths outside of atmospheric transmission windows, (ii) the microphone as detector represents a simple room-temperature device with a wavelength-independent responsivity, (iii) scattering effects are less important and (iv) the dynamic range comprises at least five orders of magnitude. Measurements are generally performed with the gas either contained in or flowed through a specially

Progress in Photothermal and Photoacoustic Science and Technology*, vol. III, Chapter 8. Bellingham: SPIE.

designed PA cell. Typically, a minimum detectable absorption coefficient $\alpha_{\min}$ of the order of $10^{-8} \text{ cm}^{-1} \text{ atm}^{-1}$, corresponding to ppb (10^{-9}) concentrations, i.e. densities of $\mu\text{g m}^{-3}$, is achieved with laser-based setups. At the cost of dynamic range this limit can be lowered further to the $<100 \text{ ppt}$ range by operating the PA cell intracavity. **Table 1** lists some gaseous compounds, laser sources used and (extracavity) detection limits achieved.

In practice, one usually deals with multicomponent samples. The analysis is done on the basis of the individual

Table 1 List and detection limits of selected gas species monitored by laser PAS under interference-free conditions

Species	Type of laser	Spectral region (μm)	Detection limit [ppb]
Formic acid	Dye	220 ^a	140
Sulfur dioxide	Dye	290–310 ^a	0.12

spectra and measurements performed at properly selected wavelengths to reduce absorption interferences. Apart from the PA signal amplitude the PA phase yields additional information for the analysis. A broad tuning range of the laser source and a narrow line width are advantageous for obtaining a high selectivity which is further enhanced for species with well-structured spectra.

Most PA studies on trace gases have been devoted to laboratory investigations on collected air samples of different origins such as vehicle exhausts or industrial emissions. If the temporal evolution of the gas composition is of interest, the air is flowed continuously through the PA cell and the laser is switched repeatedly between appropriate wavelengths that are characteristic for the absorption of the gases to be recorded. In addition to laboratory analyses and field studies yielding temporally and spatially resolved data on ambient trace gas concentrations and on their distributions are required to obtain a profound knowledge of atmospheric chemistry as well as of emission processes. Unlike lidar (Light Detection and Ranging) or long-path absorption measurements in the open atmosphere, PA schemes are not suited for remote studies but are applied to *in situ* measurements for the simultaneous monitoring of various compounds. Apart from non-laser-based PA gas

Figure 6 Temporal concentration profiles of four air pollutants during 5 days taken at the exit of a freeway tunnel. The NH_3 , C_2H_4 and CO_2 were measured photoacoustically, CO was recorded with a commercial IR gas analyser. Total traffic density and fraction of long vehicles are recorded at the bottom. sensors only a few mobile laser PA systems have been operated so far. Examples include a balloon-borne system equipped with a spin-flip Raman CO laser PA spectrometer that was employed for recording stratospheric diurnal NO concentration profiles. Furthermore, a waveguide CO_2 laser PA system was applied successfully to *in situ* measurements at a power plant where the commonly used scheme for the reduction of the emission of nitric oxides (NO_x) by injection of ammonia (NH_3) into the combustion process was to be tested. This required a reliable, fast and selective monitoring of NH_3 down to the 1 ppm level under rough measurement conditions. Studies of this type at power-, incineration- or industrial-plants play a key role for the evaluation of pollution, emission control and the testing of remedial strategies.

A fully automated CO_2 laser PA spectrometer, that is installed in a trailer, has been developed and which is operated unattended for longer time periods. The computer control ensures a proper laser wavelength selection with a long-term frequency stability of 10^{-3} cm^{-1} for ~ 70 laser transitions between 9.2 and $10.8 \mu\text{m}$ using $^{12}\text{C}^{16}\text{O}_2$ or for ~ 65 transitions between 9.6 and $11.4 \mu\text{m}$ with a $^{13}\text{C}^{16}\text{O}_2$ laser tube. The resonant PA cell is connected to a gas flow system and the air to be analysed is pumped continuously through the cell at atmospheric pressure and with a flow rate of typically $0.5\text{--}1 \text{ L min}^{-1}$. The air is not pretreated by any means except for measurements in dusty environments where a micropore filter is inserted into the gas stream at the air inlet. The humidity and CO_2 monitor in the air stream allow independent measurements of water vapour and CO_2

concentrations for comparison. Furthermore, the trailer is equipped with meteorological devices for wind and solar irradiance measurements. Hitherto, we have applied this mobile system to industrial stack emission sensing and ambient air monitoring in urban and rural environments. The stack emission measurements demonstrated the good time resolution and the high selectivity that are achieved in multicomponent analyses. In certain cases it was possible to differentiate between isomers, e.g. between *o*- and *m*-dichlorobenzene, among various other compounds, mostly VOCs, at ppm concentration levels. The selectivity is determined by the compound to be measured, and the tuning characteristics and bandwidth of the laser source.

The air in urban environments often contains numerous pollutants with rather high and varying concentrations. More recently, the mobile system was used in a harsh and noisy environment at the exit of a freeway tunnel to record gases emitted by road traffic during one week. The polluted air, filtered by a Teflon dust filter with a porosity of $1\ \mu\text{m}$, was flowed continuously through the PA cell and the laser was

tuned sequentially to wavelengths characteristic for ammonia (NH_3), ethylene (C_2H_4) and CO_2 absorption as well as to reference wavelengths with no appreciable absorption by these compounds. Concentration profiles of these three species could thus be recorded almost simultaneously with a time resolution of 10 min. As **Figure 6** shows, the temporal concentration data are clearly correlated with the independently monitored CO concentration and the traffic density. Rather high concentrations are recorded, particularly for ammonia which are most probably caused by those cars that are equipped with catalytic converters. Based on the gas concentrations and the calculated air flow through the tunnel the corresponding emission factors (mass of an exhaust component per vehicle and kilometre) were determined. These factors are $15\ \text{mg km}^{-1}$ for ammonia, $26\ \text{mg km}^{-1}$ for ethylene, $5.2\ \text{g km}^{-1}$ for CO and $201\ \text{g km}^{-1}$ for CO_2 . Such data are valuable for the estimation of the total annual emission of certain compounds from road traffic and their fractions of the total load in certain area.

Ambient monitoring in rural air requires detection schemes with very high sensitivity. So far, studies of PA

Figure 7 Spectrum of a gas mixture containing methane, methanol, ethanol, isopentane, benzene and toluene, all at ppm concentrations, buffered to 960 mbar total pressure with synthetic air (80% N_2 , 20% O_2). The measured spectrum (+) was taken photoacoustically with a difference frequency laser spectrometer based on an optical parametric oscillator (OPO) with a line width of $0.2\ \text{cm}^{-1}$. Excellent agreement is obtained with the superimposed fitted spectrum (—) using the HITRAN database for methane and the previously recorded reference spectra for the other substances. Reproduced with permission of Elsevier from Bohren A and Sigrist M (1997) *Infrared Physics and Technology* 38: 423.

sensing have concentrated on a few gases. An example concerns the *in situ* recording of ambient NH_3 , H_2O vapour and CO_2 in a heath in the central Netherlands for several months in 1989. The mobile system was applied to measurements in a rural location in central Switzerland where H_2O vapour, CO_2 , NH_3 , O_3 and C_2H_4 were recorded simultaneously with a time resolution of 10 min by using nine carefully selected CO_2 laser transitions.

A key issue in analysing multicomponent samples is the detection selectivity, which is strongly influenced by the tuning characteristics and line width of the source as well as by the measuring conditions themselves (e.g. reduced gas pressure). Laser developments have enhanced the performance substantially. A continuously tunable narrowband high pressure CO_2 laser has, for example, enabled the analysis of a mixture of six CO_2 isotopes. In one study, presented in **Figure 7**, a mixture of six hydrocarbons at ppm concentrations has been analysed by an all-solid-state laser PA spectrometer.

Studies in Life Sciences

The inherent high light scattering and the often strongly varying depth structure render biological and medical samples rather difficult for investigations with conventional spectroscopic tools. As various researchers, however, have demonstrated, PA and PT techniques can successfully be applied to media such as skin tissue, blood or plants. *In vivo* studies were performed on human skin with specially designed PA cells that allowed the study on living skin by avoiding the noise induced by pulsating blood. In particular, the absorption of UV light by protein (α -keratin) and the application of sunscreens to protect skin from UV damage were studied spectroscopically by the PA technique. The dependence on the kind of sunscreen and the amount applied (in $\mu\text{g cm}^{-2}$) were investigated as well as the rate of penetration into the skin and the time of residence in different skin layers.

The ability of PAS to detect specific compounds present in a highly diffusive medium is a great advantage for spectroscopic studies on blood. The protein haemoglobin is responsible for the transport of O_2 in blood. It exhibits three absorption bands, at 415, 540 and 580 nm, that are caused by the tetraporphyrin cycle bound to its amino acid skeleton. In **Figure 8** the typical haemoglobin spectrum is compared with blood spectra of patients suffering from anaemia, leukaemia and methaemoglobin. The deviations from normal blood are clearly visible and can complement other diagnostic results. The noncontact character of PA investigations and the fact that only minor sample amounts are required is another advantage that permits further studies on the same sample by alternative techniques.

It should be noted that no complicated preparation, treatment or any purification processes are required

before measurements. This is advantageous also for studies on living plants. Photosynthetic activities of plants and the influence of environmental stress have been investigated by various research groups. As an example, a PA apparatus has been developed to measure the oxygen evolution rate directly at a single leaf of a living plant. Environmental factors such as the effects of water stress, temperature extremes, varying light flux and

Figure 9 Temporal evolution of the emission of different gases (ethylene, acetaldehyde, ethanol and CO_2) from a cherry tomato subjected to a change from anaerobic to aerobic conditions at $t = 10.2$ h (indicated by the arrow). The emission of a reference fruit kept under aerobic conditions was subtracted to obtain the data in this figure. Reproduced with permission of SPIE from Harren F and Reuss J (1997) Applications in plant physiology, entomology, and microbiology; gas exchange measurements based upon spectral selectivity. In: Mandelis A and Hess P (eds.) *Life and Earth Sciences*. Progress in Photothermal and Photoacoustic Science and Technology, vol. III, Chapter 4. Bellingham: SPIE.

gaseous pollutants were studied in detail. A study on plant physiology is presented in **Figure 9**. The measurements were performed with a CO-laser intracavity PA arrangement. To enhance the detection specificity selective trapping was applied by leading the incoming air stream over different temperature levels of a cold trap. In the experiment, three cherry tomatoes were kept under pure nitrogen in a cuvette for 10 h before switching back to an air flow. This reexposure obviously caused significant changes of the production rates of the different compounds. This example demonstrates that the PA technique is well suited for the study of fast responses of plant tissues to changing ambient conditions.

Another area of interest where PA spectroscopy is a valuable tool concerns food science. Examples include the determination of the iron content in milk powder concentrate, moisture in instant skim milk powder, stem in ground pepper or the detection of adulterated

powdered coffee. An example of a deliberate adulteration in spices concerns the contamination of ground red paprika spice by red lead (Pb_3O_4) which not only enhances the colour of paprika but also adds to its total weight. PA studies on ground sweet red paprika have demonstrated that PA spectroscopy can be recommended as a method for rapid and gross screening for Pb_3O_4 adulterant. The current limit of detection of 2% w/w is, however, above the internationally adopted maximum permissible level and inferior to that of established techniques like atomic absorption spectroscopy (AAS) or inductively coupled plasma spectroscopy (ICPS).

Introduction

Since the discovery of the photoacoustic (PA) effect by Bell in 1880, who used the Sun as a radiation source, a foot-operated chopper for modulation and an earphone as acoustic detector, the PA effect has found numerous applications as a sensitive and rather simple technique for determining optical, thermal and mechanical properties of all kinds of samples. This article focuses on methods and instrumentation employed in *spectroscopic* applications. Since *photothermal* (PT) spectroscopy is discussed elsewhere in the encyclopedia, PT schemes are only briefly mentioned here, whereas emphasis is put on instrumentation used in *photoacoustic* spectroscopy.

Although the technique of photoacoustic spectroscopy has existed for more than a century it is particularly the advent of lasers as radiation sources with high spectral brightness that has initiated a renaissance of the PA effect. In the meantime a great variety of experimental schemes has been developed which render the PA method a very versatile spectroscopic tool.

Photoacoustic and Photothermal Schemes

Experimental Arrangements

As the photoacoustic (and related photothermal (PT)) phenomena comprise a large diversity of facets there exist various detection techniques which rely on the acoustic or thermal disturbances caused by the absorbed radiation. The selection of the most appropriate scheme for a given application depends on the sample, the sensitivity to be achieved, ease of operation, ruggedness, and any requirement for noncontact detection, e.g. in aggressive media or at high temperatures and/or pressures. **Figures 1–3** present the most typical arrangements applied for solid, liquid and gaseous samples, respectively.

Experimental schemes for PA studies on solid samples include the measurement of the generated pressure wave

either directly in the sample with a piezoelectric sensor for the pulsed regime, or indirectly in the gas which is in contact with the sample by a microphone. These most widely used setups are depicted in **Figure 1a** and **1b**. The indirect detection of the generated acoustic wave in the gas phase with the microphone is inevitable if a direct contact with the sample is not readily possible, e.g. for samples such as powders, gels or grease. The properties of piezoelectric transducers and microphones as pressure sensors are discussed below.

If the use of pressure sensors is not appropriate, because, for example, a piezoelectric transducer cannot be attached to the sample or measurements need to be done at high temperatures which hinders the application of microphones, noncontact techniques are to be applied. As shown in **Figure 1c** the induced spatial and temporal gradient of the refractive index can be sensed in this case by monitoring the deflection of a probe beam either within the (transparent) sample or directly above the (plane) sample surface (PT beam deflection or so-called mirage effect). Changes of the surface reflectivity or slight deformations of the surface (PT beam displacement) can also be detected in a noncontact manner by a probe beam. Finally, as depicted in **Figure 1d**, variations of the thermal radiation from the surface can be monitored with an infrared detector (PT radiometry). This method is of particular interest for measurements at elevated temperatures owing to the increased radiation intensity according to the Stefan–Boltzman law. Still other techniques include pyroelectric detection in thin films, thermal lensing and interferometric methods.

The typical experimental arrangement for absorption spectroscopy in weakly absorbing liquids is shown schematically in **Figure 2a**. The beam of a pulsed tunable laser is directed through the PA cell that contains the sample under study. The generated acoustic waves are detected by a piezoelectric transducer with a fast response time. Usually, only the first peak of the ringing acoustic signal is taken and further processed. Pulse-to-pulse variations of the laser power are accounted for by normalizing the piezoelectric signal with the laser power measured with the power meter after the cell.

Another area of interest is the measurement of opaque or strongly absorbing liquids. A simple open PA cell called an optothermal window was developed for this purpose as displayed in **Figure 2b**. It essentially consists

Figure 1 Typical experimental arrangements used for photoacoustic (PA) and photothermal (PT) studies on solids. As indicated one differentiates between modulated ($\sim$) or pulsed ($\square$) incident radiation. (a) Indirect PA detection by a microphone in the gas phase. (b) Direct PA detection with a PZT transducer or PVDF foil attached to solid. (c) PT sensing of the gradient of the refractive index with probe beam deflection in the (transparent) sample (probe beam 1), or above the sample surface (Mirage effect, probe beam 2). Monitoring of the generated surface displacement (probe beam 3) or of the change of surface reflectivity (probe beam 4). (d) PT radiometry senses the induced change of the IR radiation that is radiated off the sample surface.

of an uncoated ZnSe window to which an annular lead zirconate titanate (PZT) piezotransducer is glued from the bottom. The excitation beam from a laser passes unobstructed through this window and is absorbed by a droplet of the sample deposited on the other side of the ZnSe disc. The generated heat diffuses into the disk which expands. The induced stress is then recorded by the PZT transducer. Unlike in conventional transmission spectroscopy where the cell thickness is the restricting factor in dealing with strongly absorbing samples, the magnitude of the optothermal window signal depends solely on the product between the absorption coefficient and the thermal diffusion length whereby the latter can be adapted via the modulation frequency.

Figure 2 Typical experimental arrangements used for PA detection in liquids. (a) PZT detection of the acoustic wave generated by pulsed radiation in a weakly absorbing liquid. (b) Optothermal window setup applied for studies on strongly absorbing or opaque liquids with modulated or pulsed radiation.

The typical setup for gas phase measurements is shown in **Figure 3a**. A tunable laser with narrow line width, or a conventional (broadband) radiation source followed by optical filters, is used. In general, amplitude-modulated (or sometimes pulsed) radiation is directed through the PA cell. The acoustic sensor is usually a commercial electret microphone or a condenser microphone. These devices are easy to use and sensitive enough for trace gas studies with very low absorptions. Often, the detection threshold is neither determined by the microphone responsivity R_{mic} itself nor by the electrical noise but rather by other sources (absorption by desorbing molecules from the cell walls, window heating, ambient noise, etc.). However, if this latter background is known from reference measurements, the ultimate detection sensitivity is determined solely by fluctuations of the radiation intensity, and by microphone and amplifier noise. The frequency dependence of R_{mic} is usually rather small and the temperature dependence may have to be taken into account in special cases only. If modulated radiation is employed, the microphone signal is fed to a lock-in amplifier locked to the modulation frequency. Since, according to theoretical considerations, the microphone signal amplitude is proportional to the absorbed power for weakly absorbing media, the average radiation power is recorded simultaneously by a power meter for normalization.

If pulsed radiation is employed, the microphone bandwidth is often not sufficient to resolve the temporal shape of the generated acoustic pulses. However, common microphones can still be used even for nanosecond laser pulses because the length of a single acoustic pulse is essentially determined by the transit time of the acoustic wave across the beam radius. Normalized PA amplitudes are obtained by dividing the microphone

Figure 3 Typical experimental PA and PT arrangements used for gas monitoring with tunable laser sources. (a) PA detection with conventional microphone in a resonant gas cell for modulated cw radiation or in a nonresonant cell for pulsed radiation. (b) Noncontact refractive index sensing schemes with displaced colinear or transverse probe beam a (PA deflection, 1), thermal lensing (2), or colinear probe beam (PT deflection, 3).

signal peaks by the corresponding laser pulse energy that is recorded by a sensor such as a pyroelectric detector. Averaging over several pulses improves the signal-to-noise ratio. Another approach for pulsed radiation consists of using an acoustic resonator with high Q -factor as the gas cell, recording the microphone signals in the time domain but analysing the PA signal amplitudes after Fourier transformation in the frequency domain. The excited cell resonances then appear in the PA frequency spectra.

An important issue for many applications concerns the calibration of the entire PA or PT detection system. Since the PA signal depends on many factors that are not known with sufficient accuracy, a straightforward calibration is often achieved by employing a reference sample with known absorption. As an example, certified gas mixtures (trace gas diluted in a nonabsorbing buffer gas) or well-characterized dye solutions in the case of liquids are used. The situation is more difficult with solid and biological samples, particularly layered media, powders, gels or tissue. In such cases, quantitative data are difficult, if not impossible, to obtain. But even qualitative instead of quantitative spectra are often valuable, especially when other spectroscopic techniques fail owing to opaqueness or strong scattering of the sample.

It should be emphasized that numerous different versions and modifications of these general schemes have been presented in the literature. In particular, combinations of conventional methods, such as Fourier-transform IR (FT-IR) or gas chromatography (GC), with PA

detection have been reported. Some types of PA detection schemes are also implemented in commercial spectrometers.

In the following, the different components of PA spectrometers are briefly discussed.

Radiation Sources

In commercial PA spectrometers, incoherent sources such as lamps are employed in combination with filters or with an interferometer. Devices equipped with a small light bulb, with either a chopper or direct current modulation as modulated radiation source and appropriate filters to avoid absorption interferences with other species, are used as compact gas sensors, e.g. for indoor CO_2 monitoring.

However, since the generated PA signal is proportional to the absorbed (and thus to the incident) radiation power, powerful radiation sources, particularly lasers offering high spectral brightness, are advantageous for achieving high detection sensitivity and selectivity in spectroscopic applications. In the UV and visible spectral range, excimer and dye lasers have been employed, whereas in the mid-infrared (fundamental or mid-IR) wavelength range line-tunable CO_2 and CO lasers dominate the applications. Diode lasers have so far only rarely been employed in PA spectroscopy owing to their limited power. This situation may, however, change with the ongoing developments in this field. On the one hand, near infrared diode lasers with sufficient power for PAS are available for monitoring overtones and combination

bands of molecular fundamental absorptions. On the other hand, current efforts focus on the implementation of widely tunable narrowband all-solid-state laser devices in the mid-IR region for accessing the (much stronger) fundamental absorptions. Optical parametric oscillators (OPOs) and difference frequency generation (DFG) in nonlinear crystals are certainly of great interest for compact spectrometers. Furthermore, developments in quantum cascade lasers look very promising in this respect.

Modulation Schemes

Modulation schemes can be separated into the modulation of the incident radiation and the modulation of the sample absorption itself. The first technique includes the most widely used amplitude modulation (AM) of continuous radiation by mechanical choppers, electrooptic or acoustooptic modulators as well as the modulation of the source emission itself by current modulation or pulsed excitation. In comparison to AM, frequency (FM) or wavelength (WM) modulation of the radiation may improve the detection sensitivity by eliminating the continuum background caused by a wavelength-independent absorption, e.g. of the cell windows, known as window heating. This type of modulation is obviously most effective for absorbers with narrow line width and most easily performed with radiation sources whose wavelength can rapidly be tuned within a few wavenumbers. Pulsed excitation is often applied for liquids but is also of interest for gaseous samples because it permits time gating and the excitation of acoustic resonances.

In certain cases the modulation of the absorption characteristics of the sample itself is advantageous. In gas studies the Stark or Zeeman effect has been employed, i.e. by applying a modulated electric or magnetic field to the sample. The result is a suppression of the continuum background and an enhancement of detection selectivity in multicomponent samples because, for example, Stark modulation only affects molecules with a permanent electric dipole moment like ammonia (NH_3) or nitric oxide (NO) while others, possibly interfering molecules, are not affected. Finally, combinations of both amplitude and sample absorption modulation have been successfully applied, e.g. for the sensitive detection of ammonia in the presence of absorbing water vapour and carbon monoxide.

Photoacoustic Cell Designs

The PA cell serves as a container for the sample under study and for the microphone or some other device for the detection of the generated acoustic wave. An optimum design of the PA cell represents a crucial point when background noise ultimately limits the detection sensitivity. In particular, for trace gas applications many

cell configurations have been presented including acoustically resonant and nonresonant cells, single- and multipass cells, as well as cells placed intracavity. Non-resonant cells of small volume are mostly employed for solid samples with modulated excitation or for liquids and gaseous samples with pulsed laser excitation. As a unique example, a small-volume cell equipped with a 'tubular' acoustic sensor consisting of up to 80 single miniature microphones has been developed. These microphones are arranged in eight linear rows with ten microphones in each row. The rows are mounted in a cylindrical geometry parallel to the exciting laser beam axis and located on a circumference around the axis. This configuration is thus ideally adapted to the geometry of the generated acoustic waves.

Resonant cells, in combination with modulated excitation, are normally applied for gas monitoring. These cells are operated on longitudinal, azimuthal, radial, or Helmholtz resonances. The signal enhancement by the Q-factor (usually > 100) is often advantageous. Resonance frequencies lie in the kHz range resulting in resonance widths of a few Hz. Furthermore, the gas handling for the cell can be designed in such a way that the gas inlets and outlets are located at pressure nodes of the acoustic resonance which allows measurements in flowing gas with flow rates of the order of 1 L min^{-1} without increasing the noise level.

Finally, cells developed for special purposes have been suggested, such as windowless cells equipped with acoustic baffles to reduce the influence of the ambient noise or heatable cells for studying liquid samples with low volatility.

Detection Sensors

As mentioned above the acoustic disturbances generated in the sample are detected by some kind of pressure sensor. In contact with liquid or solid samples these are piezoelectric devices such as lead zirconate titanate (PZT), LiNbO_3 or quartz crystals with a typical responsivity R in the range of up to V bar^{-1} or thin polyvinylidene-difluoride (PVF_2 or PVDF)-foils with lower responsivity. These sensors offer fast response times and are thus ideally adapted for pulsed photoacoustics.

For studies in the gas phase, commercial microphones are employed. These include miniature electret microphones such as Knowles or Sennheiser models with typical responsivities R_{mic} of $10\text{--}20 \text{ mV Pa}^{-1}$ as well as condenser microphones, e.g. Brüel & Kjær models with typical R_{mic} of 100 mV Pa^{-1} . Usually R_{mic} depends only weakly on frequency. The electret microphones produced for hearing aids exhibit a rather flat frequency response between, say, 20 Hz and 20 kHz whereas the bandwidth $\Delta\nu$ of condenser microphones extends to frequencies of 100 kHz. All these microphones are thus

well suited for typical modulation frequencies in the 100 Hz to kHz range. For pulsed applications, the general relation between R_{mic} and Δv , as well as the occurrence of external noise implies a reduction of the signal-to-noise ratio for very large bandwidths so that miniature electret microphones are often appropriate detectors also in this case. The detection sensitivity can be enhanced by adding the signals of several microphones. In such a configuration the signal increases with the number of microphones used, whereas the microphone random noise decreases with the square root of their number. Since electret microphones are small and cheap, a number of them can be arranged in a still compact geometry. A further improvement of sensitivity is expected from the insertion of an electrical filter that cuts the low-frequency components below, say, 1 kHz of the signal because these components contribute less to the increase of the signal-to-noise ratio than the higher-frequency components. Finally, an adaption of the frequency response of the microphone preamplifier and amplifier stages to that of the microphone is advantageous to fully exploit all the sensed frequency contributions except noise components at frequencies not contributing to the acquired signal.

If there is a need for noncontact detection, refractive index sensing, notably thermal lensing and both PA and PT deflection, is employed. These methods use a pump beam and a probe beam (HeNe or diode laser) in either colinear or transverse arrangement as shown in **Figure 3b**. In comparison to the conventional PA method with pressure sensors, these schemes offer similar sensitivity

but require a somewhat more sophisticated setup and imply a more difficult calibration.

ω	angular frequency of modulation

Introduction

The phenomenon of the generation of sound when a material is illuminated with nonstationary (modulated or pulsed) light is called the photoacoustic (PA) effect. Photoacoustic spectroscopy (PAS) is the application of the PA effect for spectroscopic purposes. It differs from conventional optical techniques mainly in that, even though the incident energy is in the form of photons, the interaction of these photons with the material under

investigation is studied not through subsequent detection and analysis of photons after interaction (transmitted, reflected or scattered), but rather through a direct measurement of the effects of the energy absorbed by the material. Since photoacoustics measures the transient internal heating of the sample, it is clearly a form of calorimetry as well as a form of optical spectroscopy.

In the following discussion the complex PA effect will be divided into three steps:

- Heat release in the sample material due to optical absorption.
- Acoustic and thermal wave generation in the sample material.
- Determination of the PA signal in a PA detector.

A quantitative analysis of the PA signal is possible only when all three steps can be described quantitatively. Up to now this could be achieved only in a few special cases. Excitation of rovibrational levels leads to a complete transformation of the absorbed radiation into heat, whereas for vibronic excitation competing channels exist such as emission of radiation and photoinduced reactions. In this latter case, additional information on these competing channels is needed for the theoretical description.

A quantitative treatment of acoustic and thermal wave generation is usually possible only for simple excitation geometries, as can be realized by laser excitation, using the basic equations of fluid mechanics and thermodynamics.

The PA signal finally detected with a calibrated microphone for quantitative analysis is also influenced by the shape and nature of the photoacoustic cell, which impose boundary conditions on the evolution of the generated acoustic waves. However, only for highly symmetric resonant setups with high Q factors does a theoretical analysis seem to be possible. This means that for most experimental arrangements used in PAS a quantitative signal analysis cannot be achieved and more or less drastic approximations have to be introduced into the signal analysis.

Heat Release in the Sample Material Due to Optical Absorption

The interaction of photons with the material may produce a series of effects (Figure 1). If any of the incident photons is absorbed by the material, internal energy levels (rotational, vibrational, electronic) within the

Figure 1 Elementary processes occurring during PA signal generation. The absorbed photon energy is partly transformed into heat and acoustic energy.

sample are excited. The excited state may lose its energy by radiation processes, such as spontaneous or stimulated emission, and by nonradiative deactivation, which channels at least part of the absorbed energy into heat. In a gas this energy appears as kinetic energy of the gas molecules, while in a solid it appears as vibrational energy of ions or atoms (phonons). In the case of vibrational excitation of gas molecules, radiative emission and chemical reactions do not play an important role, because the radiative lifetime of vibrational levels is long compared with the time needed for collisional deactivation at ordinary pressures and the photon energy is too small to induce reactions. Thus the total absorbed energy is released as heat. However, in the case of electronic excitation, the emission of radiation and chemical reaction processes may compete efficiently with collisional deactivation. Chemical reactions may also contribute to the release of heat, and thus they may increase the PA effect. If photodissociation occurs, for example, the local increase of the number of molecules and the thermalization of the recoil energy of the fragments generate a local pressure and temperature rise.

The heat release due to optical absorption in the sample material can be modelled by a rate equation. If it is assumed that the thermalization of the absorbed photon energy can be described by a simple linear relaxation process, the heat released per unit volume and time can be determined by solving the rate equation. If the near-resonant vibration–vibration (V–V) and the

Figure 2 Timescales for the radiative emission and relaxation processes. The shaded area indicates the typical response time of a PA resonator equipped with a microphone. The thick line represents the acoustic transit time. The wavy lines depict the radiative emission and the horizontal lines the range of relaxation processes characterized by the relaxation time τ .

vibration–translation (V–T) relaxation are the fastest processes (as, for example, in many gases at atmospheric pressure), the heat power density will be proportional to the absorption coefficient and to the incident light intensity. In cases of very short laser pulses or high light intensity, optical saturation may occur. Then the heat production will be a nonlinear function of the light intensity and absorption coefficient. The timescales of the temporal evolution of the processes involved are summarized in **Figure 2**. The heat release may be delayed in gas mixtures if the excess energy of the excited molecule can be channelled by collisions to a long-lifetime transition of another species.

Acoustic and Thermal Wave Generation in the Sample Material

Sound and thermal wave generation can be theoretically described by classical disciplines of physics such as fluid mechanics and thermodynamics. The governing physical laws are the energy, momentum and mass conservation laws, given in the form of the heat-diffusion, Navier–Stokes and continuity equations, respectively. The physical quantities characterizing the PA and photo-thermal (PT) processes are the temperature T , pressure P (mechanical stress in case of solids), density ρ and three components of the particle velocity vector $\mathbf{u}$. As five equations are not enough to determine the above six quantities, a sixth equation is added, the thermodynamic equation of state in the form of $\rho = \rho(P, T)$. As the changes of ρ , P and T induced by light absorption are

usually very small compared to their equilibrium values, the equations can be linearized by introducing the deviations from the equilibrium values as new variables, by neglecting the products of the small variables and by regarding the equilibrium values as constants. Moreover, the velocity vector $\mathbf{v}$ can always be separated into two components $\mathbf{u}$ and $\mathbf{w}$, where $\text{curl } \mathbf{u} = 0$ and $\text{div } \mathbf{w} = 0$. As the heat-diffusion and continuity equations are coupled only by the nonrotational component $\mathbf{u}$ to the Navier–Stokes equation, the $\mathbf{w}$ component of the particle velocity can be omitted. The governing equations may be written then as follows:

$$\frac{\partial \theta}{\partial t} + \frac{\gamma - 1}{\beta} \text{div } \mathbf{u} - \kappa_V \nabla^2 \theta = \frac{H(\mathbf{r}, t)}{\rho C_V} \quad [1]$$

$$\frac{\partial}{\partial t} \left(p - \frac{\beta}{K_T} \theta \right) + \frac{\text{div } \mathbf{u}}{K_T} = 0 \quad [2]$$

$$\rho \frac{\partial \mathbf{u}}{\partial t} + \text{grad } p - \frac{4\eta}{3} \nabla^2 \mathbf{u} = 0 \quad [3]$$

where $\theta = T - T_0$, $p = P - P_0$, γ , β , κ_V , C_V , H , K_T and η are the new temperature and pressure variables, the adiabatic coefficient, the heat expansion coefficient, the thermal diffusivity and heat capacity at constant volume, the density of the deposited heat power, the isothermal compressibility and the dynamic viscosity, respectively. For solid materials the Navier–Stokes equation is replaced by the wave equation of the longitudinal elastic waves.

The heat power density H , released in the material as the result of all nonradiative de-excitation processes, appears as the source term on the right-hand side of the heat-diffusion equation. The spatial size and shape of the source volume depend on the light-beam geometry and on the absorption length in the material. Similarly, the time dependence of the heat source is determined by the time evolution of the light excitation and by the relaxation processes in the material. A photoacoustic effect can be generated by modulated radiation as well as by pulsed radiation. As the theoretical treatments of the two cases are different, they will be discussed separately.

Modulated PAS

In this case the intensity (or the wavelength) of the incident light beam is modulated by an angular frequency ω to generate the acoustic signal. As the modulation frequency is usually in the audio frequency range, the time delay between heat release and light intensity may be negligible. In this case the source term has the same time dependence as the light intensity. Assuming an $\exp(i(\omega t - k r))$ dependence of the variables, θ , p and $\mathbf{u}$, two independent plane wave solutions of eqns [1] and [3] can be derived: a thermal wave and a sound wave. The wavelengths of the two plane waves can be determined from the corresponding eigenvalues of the wave vector k , taking into account that the length $|k| = k$ of the wave

vector (called wavenumber) is inversely proportional to the wavelength λ ($k = 2\pi/\lambda$). The eigenvalues of the wavenumber for the thermal and sound wave may be given as $k_{th}^2 \cong -i\omega/\kappa_P$ and $k_s^2 \cong \omega^2/c^2(1 - i\omega v/c^2)$, respectively, where $\kappa_P v = 4\eta/3\rho$ and c are thermal diffusivity at constant pressure, the effective kinematic viscosity and the sound velocity, respectively. As the orders of magnitude of κ_P and c are 10^{-5} – $10^{-7} \text{ m}^2 \text{ s}^{-1}$ and 10^2 – 10^4 m s^{-1} respectively, the wavelength of the thermal wave is much shorter than that of the sound wave. That is, two types of waves are simultaneously generated: a very strongly damped thermal wave with submillimetre wavelength, and a slightly damped sound wave with wavelengths in the centimetre to metre range. The thermal wave corresponds more or less to an isobaric thermal expansion, i.e. the changes of the temperature and density are much larger than that of the pressure. Because of the large damping coefficient, this wave cannot propagate far away from the heated region; it appears only in the neighbourhood of the exciting light beam. In the sound wave a quasi-adiabatic state change propagates with the velocity of sound; here the orders of magnitude of the relative changes in pressure, temperature and density are the same. The amplitude of the periodic pressure change is proportional to the time-varying (AC) component of the released heat power density and inversely proportional to the modulation frequency.

As the average of the intensity of a modulated light beam is nonzero, the heat energy in the illuminated volume will rise continuously. Therefore, the temperature will slowly increase and the density will decrease until the heat deposition rate is equal to the loss rate due to heat conduction. This process is also governed by the heat-diffusion equation. For a closed cell the average density is constant; therefore a pressure rise will occur. This DC component of the released heat power density changes the thermodynamic state of the material, in particular in very small PA detectors ($\approx \text{cm}^3$).

The amplitude of the periodic temperature change (θ) is also proportional to the AC component of the heat power density and inversely proportional to the modulation frequency. This means that the PA and PT effects are inherently coupled; the heat deposited by the interaction of radiation with the material generates a localized temperature rise, a thermal wave and a propagating sound wave. The first two effects will result in a periodically pulsating temperature distribution.

Pulsed PAS

In the case of pulsed excitation, the absorption of photons ceases when the laser pulse is over, but the relaxation processes will continue until the full thermalization of the absorbed energy is achieved. Therefore, the duration

Figure 3 Modelling of the gas temperature distribution as a function of the radial distance from the light excitation source. The diameter of the light beam was 6 mm and the pulse duration 20 ns. The three curves represent three different time delays after illumination.

of the thermal pulse is always longer than that of the light pulse. Nevertheless, the heat pulse may be regarded as instantaneous acoustic excitation if the characteristic time of the acoustic event is much larger than the duration of the heat pulse. Two quantities characterize the acoustic process, namely the transit time τ_s of the sound through the heated volume and the response time of the PA detector. The value of τ_s is usually in the microsecond range (Figure 2), because the laser beam diameter usually does not exceed a few millimetres in PAS. The PA response time depends on the period of the eigenmodes of the detector and is usually in the millisecond range (Figure 2). As the pulse duration of most pulsed lasers is in the nanosecond range, and in many cases, such as V-V and V-T relaxation in gases, the relaxation time is also in the nanosecond to microsecond range, the source term of eqn [1] may be regarded as a Dirac-delta pulse. The governing equations (eqns [1] to [3]) can be solved by the Green's function technique, taking into account the Green's functions of both the thermal and acoustic problems. The solution is composed of a slowly broadening quasi-Gaussian temperature distribution and an outward propagating sound pulse of duration $\geq 2\tau_s$. After a short time the sound pulse will be separated from the thermal distribution, allowing the measurement of both features separately (Figure 3). The spatial symmetry of the solution depends on the shape and size of the heated region. In strong absorbers, the heated region is usually small compared to the sound wavelength; therefore mostly spherical sound waves are produced. In weakly absorbing gases, cylindrical acoustic waves are generated. The outward-propagating primary wavefront can be detected by appropriate high-frequency pressure sensors.

As the achievable sensitivity and signal-to-noise (S/N) ratio are small, the direct detection of the primary waves has no practical significance. In practice the acoustic excitation takes place inside a PA detector, and the time evolution of the acoustic signal is strongly influenced by the properties of this detector.

Determination of the PA Signal in a PA Detector

The actual solutions of the governing equations (eqns [1] to [3]) depend on the boundary conditions determined by the type and geometry of the PA detector. In gas-phase photoacoustics, the PA detector consists of a cavity and a microphone to monitor the acoustic signal. From an acoustic point of view, the PA detector is a linear acoustic system that responds in a characteristic way to an excitation. The acoustic properties of the PA detector can be determined independently using acoustic modelling techniques or by measuring them in an acoustic laboratory. Once the acoustic properties are known, the response of the PA detector for any kind of PA excitation can be determined by calculation. Although PA detectors can usually be used with both modulated and pulsed excitation, the theoretical description of the two cases will be presented separately.

PA Detectors Excited by Modulated Light

A simple PA detector consists of a cavity and a microphone to monitor the acoustic signal (Figure 4a). Even such a simple system has acoustic resonances. If the modulation frequency is much smaller than the lowest resonance, the PA detector or PA cell operates in a nonresonant mode. Such a PA cell is frequently called a 'nonresonant' cell in the literature. In this case the sound wavelength is much larger than the cell dimensions and thus the sound cannot propagate. The average pressure in the detector will oscillate with the modulation frequency. The amplitude of the oscillation may be determined by integrating eqns [1] to [3] over the volume of the detector. The pressure amplitude will be inversely proportional to the volume of the cell. The photoacoustically generated pressure can be approximated by the expression

$$p(\omega) = \frac{(\gamma - 1)\alpha W_L}{i\omega V_{\text{cell}}} \quad [4]$$

where α , l , W_L , ω , V_{cell} and γ denote the absorption coefficient of the material at the light pass length, the incident light power, the modulation frequency, the cell volume and the adiabatic coefficient of the material, respectively. In the case of a small cell and low modulation frequency, the signal may be quite large. The PA signal

Figure 4 PA setups for monitoring the PA signal with a microphone in a resonator: (a) gas or liquid, (b) solid sample in a gas microphone cell.

has a 90° phase lag with respect to the light intensity. Unfortunately, the noise also increases with decreasing frequency and volume; thus the S/N ratio will usually decrease.

As mentioned, the acoustic and thermal processes are inherently coupled. Until the cell dimensions are much larger than the size of the pulsating thermal distribution, the simple model described above can be applied. The thermal wave is usually not completely damped at the walls of the cell in the case of a very small cell and very low modulation frequency. Then both the average temperature and the amplitude of the temperature oscillation will be influenced by the heat conduction through the cell walls to the environment. As in a closed cell the pressure is proportional to the temperature, the PA signal will also depend on the heat conduction through the walls. Since the theoretical modelling of this effect is practically impossible, such small cells and very low modulation frequencies allow only a qualitative signal analysis.

A special case should be mentioned here, one of the oldest arrangements among PA detectors. Termed the 'gas-microphone cell' it is used for investigating samples of condensed materials (Figure 4b). It usually consists of a small cylinder equipped with a sample holder, a microphone and a window. The gas in the cell is non-absorbing; only the sample and the backing material (in the case of an optically thin sample) absorb the incident radiation. The PA signal is produced in an indirect way; the thermal waves generated in the solid sample are transmitted to the gas, and the periodic heat expansion of the gas above the sample surface acts as a piston and produces pressure oscillations in the closed cell volume. As the penetration depth of the thermal wave is usually much smaller than the diameter of the light beam, one-dimensional theoretical modelling is possible.

In resonant photoacoustics, an acoustic resonator with an optimized geometry such as a cylinder or sphere is used as the gas cell. Such an acoustic system has several eigenresonances, whose frequencies depend on the geometry and size of the cavity. For a lossless cylinder, the resonance frequencies of the different eigenmodes can be calculated from the equation

$$f_{n,m,n_z} = \frac{c}{2} \sqrt{\left(\frac{\chi_{m,n}}{R}\right)^2 + \left(\frac{n_z}{L}\right)^2} \quad [5]$$

where c , R and L are the sound velocity of the gas in the cavity, the radius and the length of the cylinder, respectively. The indices m , n and n_z may take the values 0, 1, 2, etc. The quantity $\chi_{m,n}$ is the n th zero of the derivative of the m th-order Bessel function divided by π .

When only one index is nonzero, the eigenmodes separate into longitudinal ($n_z \neq 0$), radial ($n \neq 0$) and azimuthal ($m \neq 0$) modes (Figure 5). In the other mixed eigenmodes the spatial distribution of the sound pressure is much more complicated.

The modulation frequency may be tuned to one of the eigenresonances of the PA detector. Such 'resonant PA cells' or detectors have found widespread application in PA trace gas measurements. Since the eigenmodes of a lossless cavity are orthogonal, the sound pressure field in a lossy cavity can be approximated in the form of a series expansion of the eigenmodes, where the amplitudes of the terms depend on frequency. In fact, each amplitude function is a resonance curve characterized by the corresponding resonance frequency and quality factor (Q factor). The first term of the series expansion determines the sound pressure below the lowest resonance. To aid understanding of the behaviour of a resonant PA cell a computer simulation is shown in Figure 6, for which the frequency dependence of the PA signal at one end of a closed cylinder filled with a strongly absorbing gas was calculated. It can be seen that several resonances (the odd-numbered longitudinal ones) lie on a nonresonant curve. For well-separated sharp resonances, only two terms of the series expansion are necessary to determine the sound pressure around a certain resonance. These are the first nonresonant term, which is independent of the spatial coordinates but depends inversely on the frequency, and the resonant term, corresponding to the selected eigenmode. This term depends on the overlap of the acoustic mode pattern and the light beam distribution, on the position of the microphone and on the quality factor of the eigenresonance. In the case of high Q factors ($Q > 100$), the contribution of the nonresonant term can be neglected and the PA signal amplitude at the

resonance frequency ω_j and at the position r_M of the microphone can be calculated as

$$p(r_M, \omega_j) = \frac{(\gamma - 1) l U_j p_j(r_M) Q_j}{V_{\text{cell}} \omega_j D_j} \alpha W_L \quad [6]$$

where l , p_j , U_j , Q_j , D_j , V_{cell} , α and W_L are the length of the light path within the cell, the pressure distribution of the j th eigenmode of the cell, the overlap integral of the light intensity distribution with p_j , the Q factor and the normalization factor of the j th eigenmode, the cell volume, the absorption coefficient and the incident light power, respectively. As the quantities in the first term of eqn [6] are independent of the light power and the

absorption coefficient, the first term may be regarded as a characteristic setup quantity, called the 'cell constant', of the PA arrangement.

Since the resonance frequency depends on the speed of sound, a temperature drift of the gas inside the cavity causes a shift of all resonance frequencies. In modulated PAS this problem can be solved by temperature stabilization, by continuous monitoring of the gas temperature or by synchronizing the modulation frequency to the resonance peak using appropriate electronics.

As the modulation frequency of a CW light source may be arbitrary, a given PA detector can operate in both the nonresonant and resonant modes. The main advantage of resonant operation is the amplification of the PA signal by the Q factor of the resonator if the modulation frequency of the incoming light is properly tuned to the selected acoustic resonance ('acoustic amplifier').

If the modulation frequency is so low that the corresponding wavelength is much longer than the dimensions of the detector, eqn [3] may be used to calculate the PA signal. Nonresonant operation is also possible by tuning the modulation frequency away from a resonance. In such cases the PA signal can be estimated by substituting $Q = 1$ into eqn [6], but a better accuracy may be achieved by taking into account the nonresonant term and at least the neighbouring eigenmodes in the series expansion.

PA Detectors Excited by Light Pulses

The absorption of a light pulse generates a primary acoustic pulse inside the PA detector. This pulse acts as a broadband acoustic source for the PA detector, exciting all eigenmodes simultaneously. If the acoustic transit time is much shorter than the period of the detected eigenmode of the resonator, the excitation of the PA signal can be regarded as instantaneous (Figure 2). In this case the slow

PA detector responds to the excitation similarly to the way in which a ballistic pendulum or galvanometer responds to force or charge pulses; a sudden rise of the PA signal followed by a slow decay can be observed. The amplitude of the first period of the sound pressure oscillation will be proportional to the released heat energy. Thus, a pulsed PA detector can be used for absolute (calorimetric) measurement of that part of the absorbed light energy that was converted to heat. As calibrated microphones are available, the absolute measurement of the photoacoustically generated sound pressure is possible. The solutions of eqns [1] to [3] can again be given in the form of a series expansion of the orthogonal eigenmodes, but in this case the amplitudes will depend not only on the frequency but also on time. A PA cell for pulsed operation is designed for optimal excitation of a selected eigenmode. This mode should be well separated from the neighbouring ones and should have a high Q factor. As the PA response in the time domain shows a very complicated behaviour, it is much better to evaluate the PA signal by converting the time signal to the frequency domain using Fourier transformation. A part of the frequency spectrum measured in a cylindrical cell, optimized for the first radial mode, is shown in **Figure 7**. The PA signal amplitude at the peak of the selected resonance can be determined from the theory as

$$p(r_M) = \frac{(\gamma - 1) IU_j p(r_M)}{V_{\text{cell}} D_j} \alpha E_L \quad [7]$$

where E_L is the pulse energy. As the fast Fourier transform (FFT) algorithm applied for calculating the spectrum delivers the average spectrum of the signal over the recorded time window, the amplitude of the resonance peak has to be corrected in order to obtain the value of $p(r_M)$. The ratio of the corrected PA amplitude and laser pulse energy depends only on the product of several geometry factors and the absorption coefficient α of the absorbing component. In contrast to eqn [6], the PA signal amplitude $p(r_M)$ in eqn [7] does not depend on the Q factor of the cavity, which cannot be calculated with high accuracy theoretically. Thus, pulsed PAS is an absolute method for measuring the absorption coefficient. Since α is given as the product of the number density N and the absorption cross section σ of the absorbing molecules, pulsed PAS can be applied for both spectroscopic studies (known N) and trace gas analysis (known σ).

Summary

The theory of PAS is sufficiently complicated that only an overview could be presented. In the theoretical description of a given PAS experiment, a separated treatment of the three physical processes, as presented here, is often not possible. Moreover, important quantities of the

Figure 7 Time-dependent PA signal recorded by a microphone (inset) and corresponding frequency spectrum of a cylindrical resonator. In the displayed frequency range, the second longitudinal (002), first radial (100), combination (102), fourth longitudinal (004) and second radial (200) modes of the resonator are detected.

theory, such as the Q factor and the overlap integral U_j , are very difficult to keep under control. Small changes in the experimental adjustment (e.g. microphone position or beam focusing) may cause considerable changes, so that the agreement between theory and experiment may be degraded. As the PA signal does not depend on the Q factor in pulsed PAS, and the Q factor, which is needed only for calculating the correction factor, can be derived from the measured spectrum, pulsed PAS is more suitable for quantitative measurements than is modulated PAS. On the other hand, the probability of optical saturation is quite high in pulsed PAS, since the pulse energy of the available laser sources is usually in the millijoule range and the corresponding instantaneous power in the kilowatt to megawatt range. Therefore, the linear dependence of the PA signal on the pulse energy must always be checked in pulsed PAS.

This article is centred on one of the most important molecular spectroscopic applications of photoionization. First, conventional photoelectron spectrometers based on the pioneering work of Turner, Vilesov and Siegbahn are reviewed, the basic building elements are shown and the principles of operation are discussed. Besides the conventional photoelectron experiment, threshold analysis and photoelectron-photoion coincidence spectroscopy as well as conceptually new techniques related to laser photoionization are discussed briefly.

Conventional Photoelectron Spectrometers

Photoelectron spectroscopy is a molecular spectroscopic method which is based on photoionization. If an atom or molecule (M) is irradiated with photons of higher energy than the ionization energy of the particle, ionization may occur. The fundamental process and its energetics are given by the following equations:

$$M + h\nu = M_i^+ + e^- \quad [1]$$

$$h\nu = IE_i + KE_i \quad [2]$$

where IE_i is the i -th ionization energy of the system studied and KE_i is the kinetic energy of the ejected electron. Complementary to mass spectrometry, where the fate of the ion is investigated, in the case of photoelectron spectroscopy the other 'reaction product', the electron, is the source of the information. As a consequence, photoelectron spectroscopy normally requires a monoenergetic radiation source, a sample inlet system, a target chamber where photon–atom/molecule interaction occurs, an electron kinetic energy analyser, a detector and a recording system. A further requirement comes from the fact that electrons lose energy through collisions with gas molecules; thus electrons can only be handled in high vacuum where the mean free path is of the same order as the characteristic geometric dimension of the spectrometer. This is normally achieved at a pressure equal to or less than 10^{-5} mbar (10^{-3} Pa). A block diagram of a typical experimental arrangement is shown in Figure 1.

Two types of photoelectron spectrometers are distinguished on the basis of the energy of the radiation sources. Energy needed to eject electrons from the valence shell (above 6 or so eV) corresponds to photon wavelengths in the vacuum ultraviolet (VUV) region of the electromagnetic spectrum. This branch of instruments is known as VUV photoelectron spectrometers, normally abbreviated as UPS. More energetic X-ray photons, commonly in the range of 1000–2000 eV, are used for core electron ionizations. This type of photoelectron experiment is called X-ray photoelectron

Figure 1 Block diagram of a photoelectron spectrometer.

spectroscopy, XPS, also named ESCA (electron spectroscopy for chemical analysis).

As far as operation is concerned there is no principal difference between the above two methods. However, the diverse fields of application – gas-phase, molecular studies on the valence shell versus solid-phase surface studies based on core electron ionizations – make sense of this distinction.

The term ‘conventional photoelectron spectrometers’ designates those UPS instruments which are technically based on the invention of Turner and Vilesov and operate with an energy resolution between 5 and 30 meV. As far as the main building units are concerned, an XPS spectrometer has a similar experimental arrangement, but a lower energy resolution (0.5–1 eV) is obviously achieved.

Light Sources

A photon source used in photoelectron (PE) spectroscopy must fulfil at least two basic requirements. First, the incident radiation must be monochromatic; the second requirement is high photon intensity. In order to achieve sufficient electron flux at the detector a source with a typical intensity of 10^{10} – 10^{12} photons s^{-1} is needed. The most commonly used source in the XPS technique is the X-ray tube, while in valence shell PE spectroscopy, resonance lamps are applied.

In the X-ray tube, radiation is generated by the bombardment of the anode with high-energy (10–15 keV) electrons. The schematic view of the widely used dual anode source is seen in **Figure 2**. In this setup the two filaments, which are at ground potential, can be heated separately. Electrons from the hot cathode hit the corresponding positive anode face. The emerging characteristic X-ray radiation leaves the source through a thin

Figure 2 A dual anode X-ray tube.

aluminium window. As the two anode faces are covered by two different metal layers, the photon energy can be changed without a break. There are many metals which can be used as anodes (see **Table 1**) but in most cases Mg or Al is used due to their narrow line width. With the use of a monochromator it is possible to filter out the satellite lines as well as the continuous radiation (the Bremsstrahlung) and to decrease the line half width to about 0.2 eV.

Ultraviolet resonance radiation may be produced by spark, direct current (d.c.) or microwave/radio frequency discharge through a rare gas. The most common type in use is the low-pressure helium d.c. discharge lamp (**Figure 3**). The discharge is initiated by applying a high voltage (~5 kV) across the discharge capillary. After the ignition period the voltage falls to 600–700 V and the gas pressure can be optimized for the generation of He(I) (21.21 eV), or He(II) radiation (40.81 eV). (The Roman numerals denote the emitting species which can be a neutral atom (I) or a singly (II) or doubly (III) ionized atom.) Since there is no transmitting material in this energy region, the beam has to pass from the cathode area into the collision chamber through a windowless collimating capillary. To prevent self-absorption and to keep the gas out of the high vacuum side, differential pumping of the lamp is necessary. The line half width of this radiation is about 1 meV.

Besides helium some other noble (or atomic) gases can also be used. Their resonance energies are summarized in **Table 2**.

Table 1 Some X-ray lines used in X-ray photoelectron spectroscopy

Anode	Transition	Energy (eV)	Line width (eV)
Be	K	108.9	5.0
Ni	L _α	851.5	2.5
Cu	L _α	929.7	3.8
Mg	K _α	1253.6	0.7
Al	K _α	1486.6	0.85

Table 2 Resonance energies of some discharge lamps

Gas	Line	Energy (eV)
He	He(I) α	21.2175
	He(I) β	23.0865
	He(II) α	40.8136
Ne	Ne(I) α	16.6704, 16.8476
Ar	Ar(I) α	11.6233, 11.8278
Xe	Xe(I)	8.4363, 9.5695
H	Lyman α	10.1986
	Lyman β	12.0872
	Lyman γ	12.7482

For some special studies (autoionization, predissociation, etc.) it is favourable to use a tunable source, and it is indispensable for threshold PE spectrometer experiments. The simplest way to generate tunable radiation is the use of a many-line or a continuous radiation source with a monochromator. A many-line source is usually a low-pressure hydrogen lamp or alternatively continuous helium or synchrotron radiation. Synchrotron radiation is produced by electron accelerators or storage rings as a consequence of radial acceleration of the electrons in a magnetic field. The main advantage of synchrotron radiation is its high intensity and broad-range tunability.

Sample Inlet Systems

Although both XPS and UPS techniques can be adapted for the investigation of either condensed or gas-phase samples, the former technique is almost exclusively applied for surface analysis while UPS is considered mainly as a gas-phase electron structure elucidation method.

The ideal solid sample is approximately 1 cm square with a mirror-smooth surface. Lumpy samples can also be measured directly while powders can be stuck onto a plastic tape or pressed into a pellet.

Regardless of the physical appearance of the solid sample, it is usually pretreated. The simplest treatment is washing the surface with organic solvents. The main drawback of this method is that the composition of the surface may change during the treatment: on the one hand, some ions may be washed out from the surface layer; on the other hand, the solvent, or even elemental carbon, may be adsorbed on the surface. These solvents, together with adsorbed water and gases, can be removed in the instrument by baking the sample in ultrahigh vacuum conditions. The most sophisticated surface cleaning method is electron or ion bombardment, and laser vapourization can also be used. These techniques are also appropriate for the etching of the surface layer-by-layer, providing the possibility for depth analysis.

In the case of a gas-phase sample a large pressure gradient must be sustained between the interaction region and the rest of the system in order to obtain a

sufficient electron current and to avoid the scattering of the electrons on the sample. The easiest way to achieve this gradient is the application of a collision chamber which may or may not be differentially pumped. In this setup the sample and the UV light pass into the chamber through a capillary or a bore and the electrons exit through a third slit directed toward the electron optics and the analyzer. The geometry of the chamber is not significant but its surface must be well cleaned, smoothed and uncharged. Local surface charges or the adsorption of dipolar molecules on the surface will shift the spectrum and decrease the resolution. These effects are most easily minimized by surface coatings of gold or colloidal graphite.

It is also possible to investigate less volatile solid samples in the gas phase. In this case the sample is evaporated close to (or in) the collision chamber. The sample can be heated by circulating hot liquid, by the heat of the discharge lamp or by a resistance oven. The temperature usually attainable by these methods is about 300 °C. The temperature can be increased further up to 1000 °C by special oven designs. In these constructions the disturbing magnetic and electric fields of the resistance heater are reduced by the use of non-inductively wound and shielded wires. Even higher temperatures (2000–2500 °C) can be achieved by laser vapourization.

Short-lived reaction products prepared *in situ* can also be studied. The sample molecules can undergo reaction shortly before ionization. Monomolecular reactions are commonly induced by UV photolysis or pyrolysis, while the feeding of highly reactive radicals into the sample vapour can cause bimolecular reactions. A well-trying variant of the latter method is the fluorine atom reaction where atoms generated from fluorine molecules in a microwave discharge outside the instrument are injected into the sample just before the ionization chamber. These methods qualify PE spectroscopy for the investigation of highly reactive molecules, transients and radicals not stable under normal conditions.

Analysis of Energetic Electrons

Basically, there are three ways of measuring the kinetic energy of electrons. The first is to measure the time needed to traverse a known distance. In the second method a retarding potential is applied to the electrons to be analysed. The third method is based on the deflection of the electrons in an electrostatic or magnetic field.

The time-of-flight (TOF) of an energetic electron over a distance of a few centimetres is very short; consequently, electronics with a response time of the order of nanoseconds are needed. This sort of kinetic energy analysis has not gained widespread application in the conventional techniques.

In retarding-field analysers, only those electrons are permitted to reach the detector which have higher energy than the retarding potential. This type of energy analysis can be performed by placing a grid in front of the detector and varying its potential. Many variations of retarding-field analysers are known; cylindrical and spherical arrangements are the most common. Analysers based on this principle yield a stepwise integral energy distribution curve in which a rise in the detected electron current indicates a group of energetically different electrons. The energy distribution can be obtained by differentiating this plot of detector signal versus retarding potential. The advantages of this type of analyser are an almost equal transmission of electrons of all energies and a large acceptance angle and consequently high sensitivity. One drawback of this method is that the examination of low-energy electrons is sometimes difficult. Furthermore, any contamination of the grids may give rise to surface potential variations which result in the loss of resolution. Retarding-field analysers can be very easily constructed but problems related to their performance limit their use for high-resolution studies.

Finally, the energies of electrons can be determined by passing them through an electrostatic or magnetic field where the deflection of the electron paths is a function of their energy. Since it is generally easier to produce a uniform electric field than a uniform magnetic field, electrostatic analysers have come to predominate in photoelectron spectroscopy. Two types of dispersive analysers are generally distinguished. In deflectors, electrons follow equipotential lines during analysis, while in mirrors electrons cross equipotential lines on moving between two electrodes.

The following part is restricted to the description of some frequently used electrostatic analysers, namely the *radial cylindrical*, the *hemispherical* and the *cylindrical-mirror* analysers.

One of the most important parameters of an analyser is the energy resolution. It may be defined as a measure of the ability of an analyser to resolve two adjacent peaks in the spectrum separated by ΔE . The resolution for deflection analysers at energy E is given by an equation of the form

$$\Delta E/E = a\omega + b(\Delta\alpha)^2 + c(\Delta\beta)^2 \quad [3]$$

where a , b and c are constants characteristic of the particular analyser; ω is the entrance and exit slit width; and $\Delta\alpha$ and $\Delta\beta$ are the angular deviation of the electron beam in the plane of deflection and the perpendicular plane, respectively.

Figure 4 shows a 127° electrostatic cylindrical analyser, one of the most frequently used in gas-phase molecular photoelectron spectroscopy. Electrons produced in the ionization chamber pass through the entrance slit

Figure 4 The 127° radial cylindrical analyser. R_1 , R and R_2 are the radius of the inner electrode, the midradius, and the radius of the outer electrode, respectively; S_1 and S_2 are the entrance and exit slits, respectively.

(S_1) and enter the analyser where they are deflected by a radial electric field produced by the electric potentials V_1 and V_2 placed on the concentric cylindrical electrodes. According to charged particle optics, focusing is achieved after an angular deflection of 127° . If E is the energy of electrons following the central path transmitted through the analyser and is related to the electrical potential V by $E = qV$, then the potentials to be applied to the outer and inner electrodes are

$$V_2 = V + 2V \ln(R_2/R) \quad [4]$$

and

$$V_1 = V + 2V \ln(R_1/R) \quad [5]$$

where R_2 and R_1 are the radii of the outer and the inner electrodes while R is the mean radius.

The majority of commercial electron spectrometers – either UPS or XPS instruments – are equipped with some form of spherical deflector analyser. The 180° spherical sector – shown in **Figure 5** – is often used because of its compactness and good resolving power.

In order to transmit electrons of energy $E = qV$ along a circular path of radius R , electrical potentials applied to the outer (V_2) and inner (V_1) electrodes are given by

$$V_2 = V[2(R/R_2) - 1] \quad [6]$$

and

$$V_1 = V[2(R/R_1) - 1] \quad [7]$$

where R_2 is the radius of the outer hemisphere while R_1 is that of the inner one.

For a hemispherical deflector, the coefficient c in the expression of resolution is equal to zero. This means that

$$V = 1.3 E \ln(R_2/R_1) \quad [8]$$

Figure 5 The hemispherical analyser. R_1 , R and R_2 are the radius of the inner electrode, the midradius, and the radius of the outer electrode, respectively. S_1 and S_2 are the entrance and exit slits, respectively.

Figure 6 The axial focusing cylindrical mirror analyser. R_1 and R_2 are the radius of the inner and the outer cylinder, respectively; w is the axial extent of the source and L is the source-detector distance.

exact focusing is achieved in the plane perpendicular to the plane of deflection.

The cylindrical mirror analyser (CMA) is shown in **Figure 6**. In this analyser, electrons emerging from the ionization region (located on the axis) pass through an annular slit into the space between two concentric cylinders. Two arrangements may be distinguished for this analyser system: axial focusing and slit-to-slit focusing. In the former case, electrons of energy E are deflected so that after leaving the exit slit they are focused along the axis. Here, focusing occurs in both the deflection plane and the perpendicular plane. A source of modest size is expected for this design. Further parameters of operation are: the injection angle is 42.3° ; the inner cylinder is earthed together with the ionization region, and the potential on the outer cylinder is

$$V = 1.3 E \ln(R_2/R_1) \quad [8]$$

The resolution is approximately

$$\Delta E/E = 1.09(\omega/L) \quad [9]$$

where ω is the axial extent of the source and L is the distance from the source to the detector.

If the source is not small and well defined, slit-to-slit focusing can be chosen. In this arrangement energy-resolving slits in the inner electrode are used and the image occurs on the surface of the inner cylinder. This design yields large signals but focusing is obtained in the deflection plane only. Slit-to-slit focusing has been successfully used in high temperature UPS studies where small signals are expected.

CMA systems consisting of two axial-focusing analysers in series have been applied for XPS instruments. This combination gives an improved resolution at the cost of sensitivity.

In all electrostatic-deflection analysers the width of the bandpass ΔE is proportional to the transmitted energy E . That is why the absolute energy resolution can be improved by preretardation of the electrons prior to energy analysis. Most spectrometers employ this technique using appropriate electron optical elements.

Detection and Registration

An electron current of less than 10^{-14} A, which is typical in photoelectron spectroscopy, can be detected with an electron multiplier. The multipliers used earlier consisting of Cu-Be dynodes have now been replaced by channeltrons. This variant of the electron multipliers is a curved glass or ceramic tube representing a continuous dynode system based on its semiconducting inner surface. The resistance between the two ends of channeltron is about $10^9 \Omega$ and a potential of about 3 kV is applied across it in operation. The attainable gain is about 10^8 . Channeltrons have the advantage of small size, low cost and ruggedness. Multichannel plates operating by the same principle are also in use. In this case, electrons within a range of energies are collected simultaneously at the focal plane of a suitably constructed analyser.

Following detection, data are collected and processed by a computer.

Operational Considerations

In photoelectron spectroscopy one must compromise between energy resolution and the intensity of the detected signal (S) relative to the noise (N). (Both quantities have been expressed in counts per second.) The resolution may be enhanced at a lower signal count rate and vice versa. The maximum attainable signal-to-noise ratio is

$$(S/N)_{\max} = S^{1/2} t^{1/2} \quad [10]$$

where t is the data collection time. The above relationship indicates that theoretically any desired resolution and signal-to-noise ratio can be achieved if sufficient data collection time is provided.

Practically, there are two modes of operation of PE spectrometers. The first is scanning the voltage V applied to the analyser electrodes. In this case, the energy resolution, $\Delta E/E$, is constant and consequently peak widths vary across the spectrum. Alternatively, if the analyser voltages are fixed while the retarding potential is scanned by the electron optics, the peak width does not change throughout the spectrum. Finally, it has to be mentioned that an accurate electron energy cannot be determined from the voltage applied to the analyser because an energy shift will be present due to contact potentials within the analyser and other part of the spectrometer. Therefore, energy calibration by introducing an inert gas together with the sample is necessary for precise ionization energy determinations.

Threshold Photoelectron Spectroscopy

As described above, conventional photoelectron spectrometers operate at fixed photon energy while the electron energy is scanned. If a continuous light source is available, the photon energy may be scanned while electrons of essentially zero kinetic energy, called threshold electrons, are detected. This is the operational principle of threshold photoelectron spectroscopy (TPES). Threshold electron detection uses a simple technique which discriminates strongly against energetic electrons while electrons formed with zero, or near zero kinetic energy, are collected very effectively with small electric fields. In practice, threshold electrons are selected by a steradiancy analyser which consists of a stainless steel collimated hole system with a specific length-to-diameter ratio. During the analysis, threshold electrons are directed to pass through the tubes while those with appreciable energy are likely to hit the tube walls and be lost. Considering the fact that energetic electrons with an initial velocity vector directed toward the detector are not discriminated by the analyser, the energy resolution using a discharge lamp is not better than 2–4 meV. This type of photoelectron spectroscopy is suited for experiments with synchrotron radiation sources as well as for photoelectron–photoion coincidence (PEPICO).

Photoelectron–Photoion Coincidence Spectroscopy

In VUV photoelectron spectroscopy, the kinetic energy spectrum of electrons is measured which provides

information about the ionic states of atoms and molecules. However, very limited information is given about the fate of the excited species formed in the photoionization process. By the use of photoelectron–photoion coincidence (PEPICO) spectroscopy a detailed analysis of the dissociation of molecular ions is possible: the fragmentation of a particular ionic state – identified through the photoelectron energy – can be directly studied. So, if ions are detected in coincidence with electrons of a given kinetic energy, the unimolecular decay of molecular ions in selected energy states can be investigated. There are two types of PEPICO instruments. In one case a light source of fixed energy, usually He(I), is used together with a dispersive electron energy analyser. Two modes of operation of this experimental setup are feasible: (i) the mass spectrum is scanned at a fixed electron energy, or (ii) a particular ion is chosen and the PE spectrum in coincidence is measured. According to the other approach, a continuum light source in conjunction with a vacuum monochromator is used and threshold electrons are collected in coincidence with parent and fragment ions so that the ion internal energy is given by $h\nu - IE$. In a typical PEPICO arrangement, which proved to be extremely powerful in the field of dissociation dynamics, threshold electrons not only serve to identify the formation of an ion of known internal energy but also provide a start signal for measuring the TOF of the ion. The ion TOF distribution contains all dynamical information such as the kinetic energy released in polyatomic dissociations, metastable ion lifetimes and collision dynamics of ion–molecule interactions.

High-Resolution Photoionization Techniques

Since the 1980s, some conceptually new photoionization techniques have appeared in the field of gas-phase investigations whose resolution is better than that of the conventional UPS technique by some orders of magnitude. Two technical novelties preceded the appearance of these techniques: the introduction of supersonic jets in photoelectron spectroscopy and the availability of high-energy lasers.

Supersonic jets have been used from the early 1950s in the fields of beam studies. According to this technique, the sample vapour is adiabatically expanded from several atmospheres into a high vacuum through a nozzle which has a diameter between 50 and 300 μm . As a result, a molecular beam with low translational (~ 1 K), rotational (~ 10 K) and vibrational (~ 100 K) temperatures is produced. This means that, according to the Boltzmann distribution, the non-ground rotational and vibrational states will be barely populated and the sample molecules

are obtained in a well-defined energetic state. Feeding a noble gas to the sample beam as a carrier enhances this cooling effect. At an early stage this method was carried out by installation of huge pumps. Nowadays, the use of a pulsed nozzle is more common. In this case the nozzle opens repeatedly for some 100 μs , and the pump has to be large enough to evacuate the chamber between two pulses only. The diverging molecular beam can be collimated or skimmed. For this purpose, separate pumping of the additional chamber (between the nozzle and the skimmer) is also needed.

The next step toward the new techniques was the availability of high-power UV lasers. In a typical setup the UV laser beam is generated as follows: an excimer or a YAG laser produces monochromatic photons, the photon energy is then tuned by a dye laser and at the last stage the selected frequency may be doubled by a crystal (e.g. by β -barium borate, BBO). The largest photon energy attainable by this method is ~ 6.5 eV. Higher energies can be reached by frequency mixing in gaseous media. Four-wave mixing and the third harmonic generations are the two typical approaches to this problem. These relatively new techniques extend the laser photon energy into the VUV region up to 19 eV.

Resonance Enhanced Multiphoton Ionization

The resonance enhanced multiphoton ionization (REMPI) technique was originally developed as a sensitive method for the investigation of excited states. In the REMPI experiment a laser excites the molecule, and then either the same laser (one-colour REMPI or $1 + 1$ REMPI) or another with a different photon energy (two-colour or $1 + 1'$ REMPI) ionizes the molecule from the

excited state. If the photon density in the well-focused laser beam is high enough, nonresonant two-photon excitation may occur and then, similar to the previous case, the same laser, or a second one, can ionize the molecule ($2 + 1$ and $2 + 1'$ REMPI). By scanning the wavelength of the first laser and measuring the amount of ions formed, information can be derived about the excited states.

Since excitation and ionization are usually carried out by pulsed lasers the obvious detection method is TOF-mass spectrometry. Formerly, linear TOF tubes were in use but they have now been replaced by reflectron TOF tubes. These tubes are folded at the middle and the ions are reflected backward by positively charged rings in the fold (see Figure 7). This type of TOF detection has two advantages. Firstly, ions of the same mass and charge but different kinetic energy will hit the detector at the same time. Secondly, the parent ions and the ions formed by fragmentation in the drift (or in the accelerating) region can be separated by tuning the reflectron voltage.

Beside ions, the detection of electrons is possible. If electrons are analysed according to their kinetic energy, the result is a new type of photoelectron spectroscopy, called REMPI-PES. This technique usually uses TOF analysers. Prolongation of the flight time of the electrons, and consequently enhanced effectiveness of separation, can be achieved by the use of an external magnetic field.

Information about the ionic states can be gained more easily by scanning with the second (ionizing) laser and monitoring the total ion intensity. This method is called REMPI-photoionization efficiency (REMPI-PIE) spectroscopy. The REMPI-PIE spectrum is a staircase function, and the conventional photoelectron spectrum can be obtained from its differentiation.

Figure 7 Schematic illustration of an experimental setup capable of performing REMPI, ZEKE and MATI measurements.

Zero Kinetic Energy Spectroscopy and Mass-Analysed Threshold Ionization

In 1984 Müller-Dethlefs and Schlag pioneered a new laser photoionization method called zero kinetic energy (ZEKE) spectroscopy. The original idea was to detect only the strictly zero kinetic energy electrons in the following way. After the laser pulse the zero kinetic energy electrons remain in the ionization chamber for some microseconds. During this time the nonzero kinetic energy electrons have left this region. After the delay the zero kinetic energy electrons are extracted by a pulse of electric field ($\sim 0.1\text{--}1\text{ V cm}^{-1}$) toward the flight tube and the detector (**Figure 7**). The latter is gated for the time of arrival of these electrons. However, practice has shown that an apparatus operating along these principles is unable to prevent the detection of electrons having a relatively small but still measurable kinetic energy (the so-called near-threshold electrons) which has a detrimental effect on the resolution. As it turned out, the mechanism described above – although it had been supposed since the late 1980s – only accurately describes the process related to the electron removal from anions (electron detachment spectroscopy). In 1988 Reiser showed that when neutral molecules are ionized, the applied pulsed field extracts the electrons from long-lived Rydberg states formed by laser excitation. (This is the so-called pulsed field ionization.) Current ZEKE instruments, utilizing the recognition of this mechanism, employ a weak electric field pulse (usually opposite in sign to the extracting field) just after the laser pulse, followed by a delay of some microseconds and then the extracting pulse. The first pulse removes the near-threshold electrons and also those in the highest-lying Rydberg states. The main extracting pulse then ionizes the remaining molecules in next-to-highest states; therefore the measured ionization energy will be somewhat smaller than the real value. The exact ionization energies can be obtained by repeated measurements at different fields followed by extrapolation to zero field. More commonly, the energies are corrected using the following equation:

$$\delta E \approx 4\sqrt{F} \quad [11]$$

where F is the applied field. This method provides photoelectron spectra with a resolution of $0.1\text{--}0.5\text{ cm}^{-1}$ ($\sim 0.05\text{ meV}$).

The extension of this technique to ions is somewhat complicated. The difficulty is due to the higher mass of the ions. In order to distinguish between ions formed by the electric field pulse and those formed by the laser pulse, longer pulses are needed. This spectroscopy is

called mass-analysed threshold ionization (MATI). The main benefit of this method is the possibility of recording the spectra of various fragment ions together with that of the parent ion.

Technically, laser excitation to Rydberg states can be performed either directly or, similarly to the REMPI technique, via an excited state, using two lasers. The advantage of the first method is that no prior information about the excited states is needed. The advantage of the second method is that investigation of chemically impure samples can be carried out since one can select the molecule of interest by varying the excitation laser energy.

Photoelectron Spectroscopy

The Encyclopedia includes a specialized article entitled 'Zero Kinetic Energy Photoelectron Spectroscopy' that describes a modern development of a long-established technique.

The principle upon which photoelectron spectroscopy (PES) is based is simple. If a molecule is excited by a high-energy photon in the ultraviolet region of the spectrum that has sufficient energy to ionize the molecule, the excited species will eject electrons. PES is the analysis of the kinetic energies of the ejected electrons. For a given excitation energy, the energy distribution of the ejected electrons reflects the distribution of accessible energy levels of the excited (ionized) molecule.

$$E_{\text{ion}} = h\nu - E_{\text{electron}} = h\nu - \frac{1}{2}m_e v_e^2$$

The first experiments in this field were performed in Russia in 1961 and in England in 1962.

With the measurement of highly resolved electron energy distributions, the orbitals from which the electrons are lost can be identified as well as vibrational progressions for the various excited ionic states.

The most commonly used UV photons are those from the He(I) line ($1s^2 2p^1 \rightarrow 1s^2$) from a helium discharge lamp, at 58.43 nm, corresponding to an energy of 21.22 eV, well above the ionization energy of organic compounds. For a thorough review of the technique and its results, the book by Turner, a founding father of the subject, should certainly be consulted.

Introduction

Photoelectron–photoion coincidence (PEPICO) is a method for energy selecting ions and studying their reaction dynamics. This subfield of mass spectrometry provides information about the mechanism and dissociation dynamics of ions. It is also a subfield of reaction kinetics because it provides a simple method for investigating reaction rates with energy-selected ions. Mass spectrometry is a useful analytical tool for investigating

the structure of molecules. It is based on the principle that a molecule, such as A-B-C-D-E-F once ionized in the source of a mass spectrometer, breaks apart into the ionic fragments A-B-C⁺, C-D-E-F⁺, A-B⁺, etc. By piecing together the various units whose masses have been measured, it is possible to reconstruct the original molecule. Such an approach works very well if the molecule is well behaved and breaks apart in a manner suggested above. However, it is common for ions to rearrange to new structures prior to dissociation. In those cases, the fragment ions observed in the mass spectrometer may not have any simple relationship to the original molecule. An example is acetol, which reacts at low energies in the following manner:

The first dissociation path yields a product ion that is clearly related to the original acetol molecule. However, the second dissociation path, the loss of HCO[•], is not possible from the original structure. Indeed, a rather major isomerization of the acetol ion must precede the loss of HCO[•]. Isomerization reactions often dominate the dissociation dynamics at low energies, when the ion is formed with an energy just above the dissociation limit. At higher energies, reaction channels that are dominant near threshold are often superseded by other dissociation paths. Thus, learning about reaction mechanisms and their variation with the ion internal energy becomes an important part of understanding the final mass spectrum. Information of this sort is provided by the PEPICO technique.

Methods for Ion Energy Selection

Review of the Methods

A number of methods for ion energy selection have been developed. They can be divided into two categories. In one, ions are first produced in the ground (or near ground) state and then excited by photons, usually in the form of laser light. Such experiments have been carried out in ion cyclotron resonance (ICR) mass spectrometers, in sector instruments, and in laser-based time-of-flight (TOF) instruments. The advantage of this method is that laser

methods can be used which provide good intensity and good energy resolution. Furthermore, it is possible to investigate very fast rate processes. The disadvantage is that parent ions are sometimes difficult to produce with little excess energy so that the final ion energy may be uncertain.

The other method involves direct ionization of the molecule to the ion energy of interest. This can be done optically by photoelectron–photoion coincidence (described below), or by charge exchange, which is a form of chemical ionization. Common chemical ionization methods include charge transfer and proton transfer.

Both methods produce ions with little internal energy. Charge transfer between a rare gas atom and a molecule deposits all of the reactant ion energy into the molecular ion as internal energy, with small amounts going into the translations. Charge transfer with ions of various ionization energies has thus been used to energy select ions. The major shortcoming of this method is that only a limited number of atomic ions can be used for this purpose.

Energy Selection by Photoelectron Photoion Coincidence

The Photoionization Process

Ionization by photons takes place by both direct ionization and by autoionization.

The processes differ in that the transition probability in the former is determined by the ionization continuum, whereas it is governed by the transition to the excited neutral state, AB^* , in the latter. Of interest to the PEPICO experiment is the decay of these autoionizing resonances and their effect on the ability to select electrons of a given energy. It has been found that, because of autoionization, ions can be prepared in Franck–Condon gap regions that are normally not accessible by direct photon excitation from either the ground neutral or the ground ionic state.

The Principle of Energy Selection by PEPICO

When a molecule absorbs a vacuum ultraviolet (VUV) photon with an energy ($h\nu$) above the molecule's ionization energy (IE), the ejected electron can have energy that ranges from 0 to $\text{IE} - h\nu$. Thus, the ion is produced with an internal energy given by

$$E_{\text{ion}} = h\nu - \text{IE} - E_{\text{el}} + E_{\text{thermal}} \quad [7]$$

where E_{el} is the energy carried away by the electron and E_{thermal} is the thermal energy of the molecule prior to ionization. It is evident from eqn [7] that an ion of internal energy E_{ion} is associated with an electron of a given kinetic energy. Thus, by detecting only ions that are collected in coincidence with an electron of a given energy, it is possible to selectively investigate energy-selected ions. This is done by placing a small electric field across the ionization region so that electrons and ions are accelerated in opposite directions. The electrons are passed through an appropriate energy analyser and collected by an electron multiplier. In the meantime, the much heavier ion requires much longer to travel down the drift tube of a TOF mass spectrometer. The time difference between the arrival time of the electron and the ion is the ion TOF. Thus, the basic information is contained in the ion TOF distribution in which the energy analysed electron provides the start signal and its corresponding ion provides the stop signal. **Figure 1** shows a schematic of a typical threshold PEPICO apparatus. The start and stop signals in **Figure 1** are usually sent to a time-to-pulse height converter (TPHC) followed by a multichannel pulse height analyser that stores and displays the ion PEPICO spectrum.

Two types of PEPICO experiments have been carried out. In one the light source has a fixed energy (e.g. the He(I) source at 21.2 eV) and the electron energies are selected by a dispersive analyser such as a hemispherical analyser. In the more versatile approach (**Figure 1**), the light source energy is tunable and the electrons of interest have zero energy. Thus the ion energy is selected by varying the photon energy while the electron energy analyser remains fixed to pass initially zero energy, or threshold electrons. The major advantages of the latter approach are (a) the better energy resolution possible with threshold electron detection, (b) the much higher collection efficiency for threshold than for energetic electrons, (c) the ability to select ions in Franck–Condon gap regions (due to autoionizing resonances) and (d) the lower level of false coincidence signals. The major disadvantages are (a) the cost and complexity of the tunable VUV source and (b) the problem with discrimination against energetic electrons whose initial velocity vector is directed towards the electron multiplier. The latter problem is suitably solved only with the use of pulsed synchrotron radiation light sources.

Electron Energy Analysis

Energetic Electrons

When a light source of fixed energy is used, the electron energy selection is made by a dispersive energy analyser such as a hemispherical analyser. The resolution of such an analyser is given by $(d/r)E_{\text{e}}$ in which d is the diameter

Figure 1 Schematic diagram of a threshold photoelectron photoion coincidence experiment. The electron resolution is determined primarily by the length of the electron drift tube and the size of the apertures.

of the input aperture, r is the average radius of the inner and outer sphere in between which the electrons pass and E_e is the energy of the electron as it passes through the analyser. Although such analysers can be run with a resolution of 10 meV, this is not really practical for coincidence experiments because of a number of factors. If an electric field of $\varepsilon \text{ V cm}^{-1}$ is applied across the ionization region in order to extract ions, then the electrons will experience a voltage drop of εd_{ph} across the photon beam of width d_{ph} , thus limiting the resolution to εd_{ph} . In order to avoid this, the ionization region must be kept field free and the ions extracted by a pulsed electric field applied whenever an electron is detected.

Threshold Electrons

The principle of threshold electron detection is totally different from the energy analysis of energetic electrons. A threshold has no initial kinetic energy, and thus must be extracted from the ionization region with an electric field. Because such an electron can be accelerated directly towards the detector, it can be collected with near 100% efficiency. On the other hand, energetic electrons will have a distribution of initial ejection angles which, as a first approximation, can be assumed to be isotropic. The application of a small electric field will not be sufficient to bend the electron trajectories towards the detector; thus most of the energetic electrons will be lost. Only those electrons whose initial velocity is directed towards the detector can be collected. (These are the electrons that are collected in a fixed photon energy PEPICO experiment.) It is possible to collect threshold electrons with good discrimination against energetic ones by simply passing them through small apertures in a long pipe. No real energy analysis is required. An important benefit for the PEPICO experiment is that a constant electric field can be applied to the ionization region, which gently extracts the threshold electrons and at the same time extracts the ions.

The electron energy resolution, or the electron collection efficiency, $R_{el}(E_0)$, as function of the electron's

initial energy can be derived for an analyser that consists of a single acceleration region and a long drift region of length l and with apertures of diameter, d . If we assume a point source for the electrons within this electric field, the electron collection efficiency is given by

$$R_{el} = 1 - \left[1 - \left(\frac{E_g}{E_0} + 1 \right) \sin^2 \phi_c \right]^{1/2} \quad [8]$$

$$E_0 > E_g \tan^2 \phi_c$$

$$R_{el} = 1 \quad E_0 \leq E_g \tan^2 \phi_c \quad [9]$$

where E_g is the energy gained by the electron as it is accelerated out of the ionization region, E_0 is the electron's initial kinetic energy and ϕ_c is the planar critical collection angle, which for large l is approximately $d/2l$.

A resolution of 25 meV is readily attained with electric fields of 10 V cm^{-1} , an electron drift tube of 10 cm and apertures of 3 mm. The real power of this method is realized when the light source is pulsed with high repetition rates, as is possible with radiation from a storage ring of a synchrotron. In that case, an additional energy analysis, TOF, can be used to improve the resolution to a few million electron volts.

Counting Statistics – Real and False Coincidences

If an electron of the appropriate energy is collected but its corresponding ion is (for whatever reason) not collected, then it is possible that some other, totally unrelated ion can provide the stop signal. Such a coincidence event is called a 'false' coincidence because the electron and ion come from different precursor molecules. In a DC extraction field, these false coincidences appear at random times and thus provide a uniform background to the coincidence TOF mass spectrum. These can be easily distinguished from the real coincidences, which appear at a TOF that is determined by the ion's mass. However, if the ions are extracted with a voltage pulse, then both real and

false ions will have the same TOF and are correspondingly more difficult to distinguish.

The number of false coincidence events depends upon the total ionization rate. If the total ionization rate is 10^6 ions s^{-1} , then an electron and ion pair are born every microsecond. Because most electrons are of the wrong energy, they are rejected so that the observed electron count rate is much smaller than 10^6 . However, all ions can in principle be detected and, since it takes about 5 μs to extract an ion from the ionization region, it is clear that there are many ions that are able to provide stop pulses. A total ionization rate of 10^6 is not unreasonably high for a fixed light source PEPICO experiment because the helium resonance lamp is very intense and thus generates a very large ion signal.

PEPICO experiments work best with a continuous light source that is relatively weak, and with very high collection efficiencies for both electrons and ions. A pulsed source such as a 10 Hz pulsed VUV laser would not work because each laser pulse would produce many electrons and ions within a 10 ns interval. Thus, it is impossible to distinguish which electron is associated with which ion.

One of the unique features of PEPICO is the ability to determine the collection efficiencies and thus the absolute total ionization rate, N_T . The ion and electron collection efficiencies (E_i and E_e) can be calculated from the coincidence count rates (N_c) and the observed ion and electron count rates (N_i and N_e). They are given by

$$\text{Ion collection efficiency} = E_i = N_c/N_e \quad [10]$$

$$\text{Electron collection efficiency} = E_e = N_c/N_i \quad [11]$$

Once the efficiencies are known, the total ion production rate is given by $N_T = N_i/E_i$, or N_e/E_e . These calculations make one important assumption, which is that the electrons and ions extracted from the ionization region originate from the same ionization volume.

The Ion TOF Distribution

The information content of the PEPICO technique lies in the ion TOF distribution. Not only does the TOF distribution disperse ions according to their masses, but it also provides information about the kinetic energy released in a dissociation, and about the dissociation rate of the ion if it is in the range of 10^4 – $10^7 s^{-1}$. Examples of such data are discussed below.

The Ion Breakdown Diagram

A breakdown diagram is a plot of the fractional abundances of ion masses as a function of the ion internal

energy. An example is shown in Figure 2 for the case of chromium hexacarbonyl. When the photon energy is above the molecule's ionization energy but below the first dissociation limit, the TOF distribution shows only one peak, the parent ion. Once the ion internal energy exceeds the dissociation limit, the parent ion signal disappears and in its place the first fragment ion appears, $Cr(CO)_5^+$, which is associated with the loss of a CO molecule. The crossover energy at which parent and fragment ion intensities are equal provides a very precise means for determining this first dissociation limit.

As the photon energy is increased, the excess energy is partitioned between the translational, rotational and vibrational energies of the fragments. The rotational and vibrational energy remaining in the $Cr(CO)_5^+$ increases with photon energy until it exceeds the next dissociation limit for the loss of a second CO fragment. Because in the energy partitioning most of the energy remains in the vibrational modes of the larger fragment, the $Cr(CO)_5^+$ signal decreases to nearly zero while the $Cr(CO)_4^+$ ion takes its place. This continues up to the final loss of the last CO unit. Because of energy partitioning, each new onset is more gradual than the previous one. It must be pointed out that this breakdown diagram is very peculiar and not at all typical. It is characterized by the following successive dissociation paths:

Figure 2 A breakdown diagram of chromium hexacarbonyl ions obtained by PEPICO. This ion dissociates by a sequential mechanism. The heats of formation of the various ions can be determined from the energy onsets of their formation. Reproduced with permission from Das PR, Nishimura T, and Meisels GG (1985) Fragmentation of energy selected hexacarbonylchromium ion. *Journal of Physical Chemistry* 89: 2808–2812.

Figure 3 The PEPICO TOF distribution of C_2H_5^+ ions from energy selected $\text{C}_2\text{H}_5\text{I}^{*+}$ ions at various energies above the dissociation limit for $\text{I}^{\bullet}$ loss. The solid lines that fit the experimental points are single energy release distributions. From these data, the whole distribution of product translational energies could be determined. Reproduced with permission from Baer T, Büchler U, and Klotz TCE (1980) Kinetic energy release distributions for the dissociation of internal energy selected $\text{C}_2\text{H}_5\text{I}^{*+}$ ions. *Journal de Chimie Physique* 77: 739–743.

widths broaden. The solid lines in this figure are TOF distributions expected for single kinetic energy releases of $9n^2$ ($n = 2, 3, 4, \dots$) meV. Because of apertures, ions with significant off-axis velocities will be stopped. Thus, each TOF peak for ions with KER greater than $n = 2$ will appear as a doublet, which accounts for the forward and backward ejected ions.

One of the most useful applications of peak widths in the TOF distributions is in distinguishing an ionization from a dissociative ionization process. This is particularly useful in the case of photoionization of clusters. An example of such a study is the case of ArCO^+ , which can arise from a variety of processes in a molecular beam expansion of Ar and CO gases, including those shown in eqns [18]–[20].

If one is interested in the appearance energy or the thermochemistry of the ArCO^+ ion, it is necessary to know by which process this ion is created. In each of the three reactions, the product ion mass is the same. However, the first reaction can be distinguished from the dissociative ionization processes because its TOF peak is expected to be narrow, whereas the latter two reactions will impart kinetic energy to their fragments and thus result in broadened TOF peaks. This is illustrated in Figure 4. The narrow peak with a width of 34 ns is due to

Figure 4 The PEPICO TOF distribution of ArCO^{*+} ions from various precursor cluster ions. The sharp peak is due to the direct ionization of ArCO dimers, whereas the broad peak with a width of 160 ns is due to dissociative ionization of Ar_2CO trimers. Reproduced with permission from Mahnert J, Baumgartel H, and Weitzel KM (1997) The formation of ArCO^+ ions by dissociative ionization of argon/carbon monoxide clusters. *Journal of Physical Chemistry* 107: 6667–6676.

reaction [18], while the broad peak with a width of 160 ns is due to the dissociative processes. By this approach, an onset of 13.03 eV for the ArCO^+ ion from ArCO could be measured. In addition, by measuring the width of the broad peak as a function of the cluster ion energy, it was possible to extrapolate the kinetic release in the second reaction down to the threshold (as shown in Figure 5).

A similar study found that Ar_n^{*+} ($n > 2$) ions produced in a supersonic expansion of argon originated exclusively by dissociative photoionization from higher-order clusters. Only in the case of Ar_2 could ions of that mass be produced without the accompanying dissociation. This was obvious from the broad peak widths, which showed no evidence of any narrow components for Ar_n^{*+} other than for $n = 2$.

Ion Dissociation Rate Measurements

The dissociation rates of metastable ions can be measured by PEPICO because the ion TOF distribution is very sensitive to the position of dissociation in the acceleration region. Ions that dissociate rapidly gain the full kinetic energy in the acceleration region, whereas ions that dissociate some distance into the acceleration region end up with less kinetic energy because it is partitioned between the ion and neutral fragments. Typical ion TOF

Figure 5 The derived kinetic energy release from the energy-selected $\text{Ar}_2\text{CO}^{*+}$ ions as a function of the trimer ion internal energy. The solid line is a calculated kinetic energy release based on the statistical theory of dissociation: phase space theory (PST) or the version of PST due to C.E. Klotz. AP is the threshold energy for ArCO^+ formation. The onset leads to a heat of formation of the trimer ion. Reproduced with permission from Mahnert J, Baumgartel H, and Weitzel KM (1997) The formation of ArCO^+ ions by dissociative ionization of argon/carbon monoxide clusters. *Journal of Physical Chemistry* 107: 6667–6676.

distributions of products formed from metastable $C_6H_6^{*+}$ ions are shown in **Figure 6**. The benzene ion dissociates via four major paths at low ion energies:

Only the latter two fragments are shown in **Figure 6** because the mass difference between the parent ion and the H and H_2 loss channels are not sufficient to be resolved in this low-resolution TOF spectrum. However, what is evident is the asymmetry of the $C_4H_4^{*+}$ and $C_3H_3^+$ ion TOF distributions. The peak shapes can be modelled (solid lines in **Figure 6**) knowing the mass of the ions, the electric field, the length of the acceleration and drift distances, and the ion dissociation rate, which is an adjustable parameter. As the ion energy is increased from 14.85 eV to 15.32 eV, the rate constant increases from 0.16 to $\sim 1.1 \mu s^{-1}$.

Such data collected at a number of ion energies lead to a $k(E)$ vs E curve shown in **Figure 7**. The solid lines in this figure are the results of a statistical theory calculation using the Rice–Rampserger–Kassel–Marcus (RRKM)

Figure 6 (k = rate constant; E_T = total ion energy) The PEPICO TOF distribution of $C_3H_3^+$ and $C_4H_4^{*+}$ ions from energy-selected $C_6H_6^{*+}$ ions. The asymmetric TOF distributions are a result of the slow reaction of the metastable ions. The solid lines are calculated distributions using the mean ion dissociation rate as an adjustable parameter. Reproduced with permission from Baer T, Willet GD, Smith D, and Phillips JS (1979) The dissociation dynamics of internal energy selected $C_6H_6^{*+}$. *Journal of Chemical Physics* 70: 4076–4085.

formulation. Studies such as this on many molecules have shown that the RRKM theory is extremely useful and accurate in predicting the dissociation rate constants of ionic reactions. It is also very useful for determining the onset of dissociation. This is of interest both for fundamental reasons as well as for a very practical one. Dissociation onsets are often used to determine thermochemical properties of ions and free radicals. Consider the reaction

in which the stable molecule is dissociatively ionized to the ion A^+ and a free radical, $B^{\bullet}$. By energy conservation, the heats of formation of the three species in eqn [22] are related to the minimum energy of dissociation (DE) by

$$DE = \Delta H_f(A^+) + \Delta H_f(B^{\bullet}) - \Delta H_f(AB) \quad [23]$$

Thus, if any two of the three heats of formation are known, the third can be calculated from the measured dissociation energy, DE. Many heats of formation derived using this approach have been reported. However, the validity of this method depends upon a rapid dissociation of the

Figure 7 The dissociation rate constants of $C_6H_6^{*+}$ ions as a function of the ion internal energy. The solid lines are calculated rate constants using the statistical theory of unimolecular decay (RRKM). Reproduced with permission from Baer T, Willet GD, Smith D, and Phillips JS (1979) The dissociation dynamics of internal energy selected $C_6H_6^{*+}$. *Journal of Chemical Physics* 70: 4076–4085.

molecular ion. What is actually measured is the appearance energy, AE, of the product ions which is always greater than DE. Ions prepared just above their dissociation threshold often fragment very slowly (e.g. $k < 10^4 \text{ s}^{-1}$) so that no A^+ ions will be observed since ions are collected in just a few microseconds after their formation. It is not until the ion energy reaches a level at which the dissociation rate constant, k , exceeds 10^4 s^{-1} that A^+ ions are observed. An effective means for circumventing this problem is to measure the dissociation rate constant as a function of the ion internal energy and to extrapolate this $k(E)$ curve to the dissociation onset by use of the statistical theory of unimolecular decay. The extrapolations in **Figure 7** predict that the true onsets for these dissociation channels for loss of $H^\bullet$, C_2H_2 and $C_3H_3^\bullet$ lie at 13.7, 14.32 and 14.47 eV, respectively. It is apparent that these onsets are well below the data in **Figure 7**, which were all collected above 15 eV because below this energy no fragment ions were observed. This is an example of the ‘kinetic shift’ that has shifted the onset towards higher energy because the dissociation rate constant at threshold is too slow.

Dissociation rate measurements are also very useful for determining the mechanism of ionic dissociation reactions. If the ion isomerizes prior to dissociation, the rate constant will be slower than predicted by the RRKM theory. Often it has proved possible to determine experimentally the energy of the isomerized structure by modelling the $k(E)$ curve with the RRKM theory. The reliability of such studies is greatly enhanced by the use of *ab initio* molecular orbital theory, which provides valuable input for the RRKM theory calculations.

ΔH_f°	standard enthalpy of formation
λ	wavelength

The formation of ions in a mass spectrometer ion source can be accomplished by a variety of ionization methods. Photoionization of a molecule or atom involves the absorption of a vacuum ultraviolet (VUV) or soft X-ray photon. Depending on the wavelength (λ) of the photon, whose energy E is given by the Planck–Einstein relationship,

$$E(\text{eV}) = \frac{hc}{\lambda} = \frac{1239.85}{\lambda(\text{nm})} \quad [1]$$

both ionization and subsequent fragmentation of the ionized molecule may occur. It is also possible to induce fragmentation of an initially formed ion by absorption of a single photon, or by the sequential absorption of a number of photons of equal or different wavelengths, in a photodissociation process. One particularly useful advantage of using a photon beam for ionization of a neutral, or dissociation of an ion, is that the amount of energy deposited depends only on the wavelength, which can be precisely measured and controlled. For this reason, the techniques of photoionization and photodissociation mass spectrometry are primarily used for fundamental energetic, kinetic and structural studies, although there are various analytical applications that can also benefit from these particular experiments. Because mass spectrometers used for photoionization and photodissociation experiments are not widely available, they are generally designed and constructed in the laboratory engaging in the particular studies.

A major source of energetic information is the photoionization efficiency (PIE) curve in which the relative number of photoions produced per number of photons transmitted is measured as a function of photon wavelength (energy). A typical PIE curve is shown in Figure 1.

Apart from yielding accurate thermochemical data, the PIE is also a convenient means of studying the energy

dependence of a range of gas-phase unimolecular processes, which include those involving weakly bound clusters and ion–neutral complex intermediates. The detection of near zero-energy photoelectrons coincident with photoion formation (threshold PEPICO (photoelectron–photoion coincidence)) provides a direct measure of the internal energy of the initially formed ion; for many systems similar information can be obtained from the corresponding first differential PIE curve.

Photodissociation experiments involve the photon-assisted decomposition of a preformed ion beam with subsequent detection of the resulting fragment ions. To observe photodissociation with a mass spectrometer it is necessary that the photoabsorption process produces an excited state of the precursor ion above its lowest dissociation threshold. The dissociation should also be relatively fast compared to any other competing process, such as relaxation. The photodissociation spectrum of an ion, which is a measurement of the photodissociation efficiency as a function of photon energy, is related to the photoelectron spectrum for the corresponding neutral molecule and is comparable to the ion absorption spectrum. However, unlike photoabsorption experiments, photodissociation is a more sensitive technique for obtaining structural information because any small changes are not superimposed on a relatively large signal. There is also less interference from other contaminating species, such as ion–molecule reaction products.

Photodissociation spectra of excited ionic species that predissociate contain more structural information than those resulting from a direct dissociation. Unfortunately, there are few ions that undergo suitable predissociation processes. Time-resolved photodissociation, which involves the monitoring of fragment ion build-up following photoexcitation, provides a direct measure of the bond cleavage kinetics, from which bond strength information can be obtained. These experiments, in conjunction with Rice–Ramsperger–Kassel–Marcus (RRKM) calculations, can also help to determine dissociation thresholds.

Photoionization

Sample Introduction

The simplest method for introducing a sample into an ion source is via an effusive beam through a pinhole or

Figure 1 Photoionization efficiency curve with (inset) an expanded threshold region for the molecular ion from cyclopentanone. The photoions detected below the adiabatic ionization energy IE_{ad} (indicated by the arrow) are due to hot bands.

needle valve. For some experiments it is advantageous to cool the sample prior to introduction to minimize problems associated with the thermal population of vibrationally and rotationally excited species. Because of condensation problems, this method is not applicable to molecules with relatively high freezing points. However, the use of a super-sonic molecular beam for sample introduction can result in a substantial internal cooling effect, with rotational and vibrational temperatures below 20 K being achieved for polyatomic molecules. This significantly reduces the interference from low-energy tailing, called hot band structure, that is usually observed in the pre-threshold region of a room-temperature PIE curve (see **Figure 1**). Various free radicals and transient molecules have been studied by photoionization, although they often require special methods of preparation and introduction. Because these species are usually present at very low concentrations, it is preferable to have access to a high-intensity photon source. A molecular beam can also facilitate the production of clusters for investigation by photoionization.

Photon Sources

Several different laboratory light sources can be used for VUV studies. These usually involve a gas discharge, which may produce either a continuum or a discrete-line emission spectrum. Although the output of light is generally much greater for a line spectrum, these cannot be used for very high-resolution studies because PIE measurements are then restricted to the finite number of emitted photon energies available. A commonly used

photon source is the hydrogen many-lined spectrum (pseudocontinuum), which is shown in **Figure 2**. This is produced by a simple DC discharge in hydrogen at a relatively low pressure (<1 kPa), and produces usable photons in the energy range of 7–14 eV.

Care must be exercised with the data processing when using such a discrete-line source as it is possible for false structure to be generated in the PIE curve, particularly in the low photon intensity regions (e.g. 9.3–9.6 eV) of the lamp.

Two continuum sources that have been used for photoionization studies are the argon continuum (8–12 eV) and the Hopfield helium continuum (12–21 eV). Both of these involve emission from a transient diatomic molecule generated via a pulsed high-voltage, high-pressure (>10 kPa) rare gas discharge. As for the hydrogen pseudocontinuum, a typical photon intensity is approximately 10^9 – 10^{10} s $^{-1}$, which is substantially lower than the photon intensity obtained with either an electron monochromator or a conventional electron ionizing source.

Experiments involving continuous emission at energies above 21 eV require the use of synchrotron radiation, in which light is emitted from rapidly moving electrons accelerated in a circular path. The spectral distribution and intensity available from the electron storage ring vary depending on a number of different operating parameters. However, usable photon energies typically extend from the visible into the X-ray region, with intensities significantly greater than those of comparable gas discharge lamps. The high intensity of synchrotron radiation has proved particularly successful for photoionization studies involving low concentrations of free radicals.

Figure 2 The many-lined molecular hydrogen pseudocontinuum.

The use of lasers as a photoionization light source has been limited by the availability of a suitable tunable VUV laser. The fundamental problem in developing such a high-energy laser is that the laser action becomes increasingly difficult to sustain as the photon energy is increased. Consequently, most laser-based photoionization experiments have involved multiphoton techniques in which the energies of several photons are combined. A commonly used method for the ionization of molecules is resonance-enhanced multiphoton ionization (REMPI), in which the laser frequency is tuned to an excited neutral electronic state. This greatly enhances the cross section for ionization. One photon is involved in the excitation process while a second photon, which may have a different wavelength (colour), is used to ionize the excited molecule.

Monochromators

For energetic studies it is necessary to select a given photon wavelength from the light source with a monochromator. Although there are numerous types available, it is preferable to use a design in which the entrance and exit slits remain in a fixed position relative to the mass spectrometer. The image at the exit slit should also stay in focus. Two monochromators that essentially satisfy these requirements are the Seya–Namioka and the near-normal-incidence type. The Seya–Namioka monochromator, in which wavelength selection is accomplished by the simple rotation of a diffraction grating about its centre, unfortunately suffers from an astigmatic and curved image at the exit slit, which result in a decrease in both intensity and resolution. Despite its more complex scanning mechanism, the near-normal-incidence monochromator is better suited for high-resolution studies. Photoionization experiments with monochromator resolutions better than 0.002 nm have been reported, although a typical operating resolution is 0.1 nm, which corresponds to 0.008 eV for a photon with an energy of 10 eV.

Figure 3 Vacuum ultraviolet reflectance curves for different grating surfaces.

Wavelength calibration is normally done using atomic lines generated in the emission spectrum of the lamp.

The concave diffraction gratings used in these monochromators are usually optimized to maximize the light intensity over a selected operating wavelength region. This includes the selection of a blaze angle and a particular overcoating of the ruled surface. As shown in **Figure 3**, an aluminium surface with a thin film of MgF_2 or LiF provides the highest reflectance for photon energies below 12.0 eV. Metal coatings, such as platinum, are best used for experiments that extend to higher energies. The dispersion (resolution) of a grating depends on both its radius of curvature and the ruled line density. Typical values for these parameters are 1 m and 1200 grooves mm^{-1} , respectively. Ghosting effects and the amount of scattered light can be reduced with a grating that has been holographically ruled.

If a high-pressure gas discharge is being used as the VUV light source, it is preferable to isolate the monochromator from the lamp. Apart from the problems

associated with interfacing the lamp and monochromator to the vacuum environment of a mass spectrometer, self-absorption of light by the discharge gas greatly reduces the available photon intensity. In some cases the installation of an optical window at the entrance slit can be used to avoid this, although the choice of window material is somewhat restricted. A LiF filter can be used for photon energies up to 12.0 eV, although for photoionization studies above this sharp cut-off energy the monochromator needs to be windowless. This requires the use of substantial vacuum pumping systems to maintain a satisfactory pressure differential between the lamp and the monochromator, especially when a wide entrance slit is being used. Because the storage ring of a synchrotron light source is operated under a high vacuum, it does not suffer from this particular interfacing problem. However, the wide energy range of the generated light can result in contamination of a PIE curve by second-order or higher-order diffraction, requiring analytical removal during the data reduction. Alternatively, for low-energy studies an appropriate filter, such as a LiF window, can be used to effectively remove this interference.

Photon Detectors

When conducting PIE experiments it is essential to monitor the total amount, or a representative sample, of light that is being used for the ionization process. The simplest device involves counting the photoelectrons emitted from either a simple irradiated metal plate, or, for low levels of light, via a discrete or continuous dynode (channeltron) electron multiplier. However, both methods require calibration of the photocathode spectral response. Electron multipliers have also been developed in conjunction with special photosensitive cathodes for operation well into the vacuum ultraviolet region. Because they are relatively insensitive to light of wavelengths greater than 300 nm, which is approximately the limit of solar radiation reaching the earth's surface, they are often referred to as 'solar blind' photomultipliers. Again, the photoelectric yield is wavelength dependent and must be calibrated.

An alternative approach to photon detection is to use a phototransducer in conjunction with a conventional photomultiplier. This involves measuring the fluorescence produced following irradiation with VUV light. A particularly convenient and widely used phosphor is sodium salicylate, which has a high fluorescence efficiency and nearly constant quantum yield over a wide photon energy range (5–35 eV). Periodic replacement of this phosphor is required as its low-wavelength efficiency deteriorates with time in a typical vacuum environment.

Mass Analysers

Several different types of mass analyser have been used for photoionization studies, including quadrupole, magnetic

sector and time-of-flight (TOF) mass spectrometers. The technique of time-resolved photoionization mass spectrometry uses a quadrupole ion trap to store ions for a selected time prior to detection, which greatly increases the threshold sensitivity for slow fragmentation processes. Many experiments require extended periods of data acquisition so that a high mass stability is vital. In addition, because photoionization produces only small numbers of ions in the ion source, it is important to ensure that the mass analyser has a high ion transmission efficiency. The probability of photoionization can be enhanced by increasing the sample pressure in the ion source. However, to minimize absorption corrections and collision-induced effects, such as ion–molecule reactions and collisional activation, maximum pressures are generally restricted to below 0.1 Pa.

The quadrupole mass filter is an inexpensive and compact device in which the ion source operates at ground potential, making it convenient for interfacing to a monochromator. The ion optics for entry to the quadrupole RF/DC field are relatively straightforward, while it is a simple procedure to alter the mass resolution and maximize the ion count rate for a particular experiment.

A magnetic mass analyser is considerably more expensive and physically larger than its quadrupole counterpart. In normal operation the ion source operates at a high positive voltage so that the monochromator interface region must be carefully designed to ensure that photoelectrons ejected from either the photodetector or any metal surfaces are not accelerated into the ion source to produce spurious ionization. For maximum ion transmission it is necessary to use an ion-optical lens, such as an electrostatic quadrupole, to focus the ions from a wide area into the narrow entrance slit of the mass spectrometer. The magnetic mass spectrometer, unlike a quadrupole mass filter, is able to detect metastable ions, which makes it particularly useful for the study of unimolecular fragmentation processes.

The TOF mass spectrometer is well suited to the mass analysis of ions produced from a pulsed source. In contrast to scanning mass analysers, the TOF detects all ions sampled from the ion source. For this reason it is widely used for coincidence PEPICO measurements and various laser ionization experiments. The pulsed nature of synchrotron radiation also lends itself to TOF photoionization studies. Peak shapes for different ions in a TOF mass spectrum can provide valuable information about their kinetic energy distributions.

Ion Detectors

Various ion multipliers have been used to detect mass-selected photoions. These include the discrete dynode electron multiplier, the continuous dynode channeltron and the Daly detector, which uses a combined

Figure 4 Schematic representation of a Daly scintillator/photomultiplier ion detector.

scintillator/photomultiplier to monitor the fluorescence produced from secondary electrons generated by ion bombardment of a high-voltage conversion electrode (**Figure 4**). Because of the small numbers of ions generated in photoionization experiments, pulse counting, rather than analogue, techniques are usually employed. The digital method of detection is more immune to noise, although it is preferable to use a multiplier that has a low background pulse count rate, typically less than one pulse every 10 s. Stray external magnetic fields, such as those encountered with a magnetic mass analyser, can impair the multiplier performance and require appropriate shielding.

Data Processing

Most photoionization experiments require extended data acquisition to increase both the ion count statistics and the signal-to-noise ratio to acceptable levels, particularly in the threshold region where the photoion count rate can be extremely low. It is not unusual for some experiments to last for 24 hours or more. However, as the reduction in random noise only increases as the square root of the accumulated counts, there is a practical limit to the improved quality of data obtained using this technique.

The PIE curve provides the basis for obtaining precise gas-phase thermochemical information, such as bond energies, proton affinities, and cationic and neutral heats of formation. Because the ionization process is governed by the Franck–Condon principle, the most probable process will involve a vertical transition. Depending on the geometry change following ionization, this may not always correspond to the adiabatic (minimum) ionization energy (IE), as shown in **Figure 5**.

Because the precursor molecules have a thermal energy distribution, ionization will not all occur from the neutral ground state, resulting in ions being produced

Figure 5 Single ionization of a molecule AB, showing the adiabatic, the vertical and a hot band transition.

below the true ionization threshold energy (**Figure 5**). This is observed as pre-threshold hot band structure in the PIE curve and will typically extend over a range of 0.1 to 0.2 eV for a polyatomic molecule at room temperature (see **Figure 1**).

When variable-energy photons are used for ionization it is possible for autoionization to occur. This is the result of ionization from an excited neutral Rydberg state above the ionization threshold. Auto-ionization processes are observed as peaks in the PIE curve and can often complicate the assignment of the adiabatic ionization energy. **Figure 6** shows the effect of autoionization in the PIE curve for xenon. The structural profiles are similar to those observed in comparable photoabsorption experiments.

Apart from the higher resolution relative to similar electron ionization experiments, photoionization has an additional advantage in that there is a finite cross section at threshold, making it easier to detect the actual ionization onset. This also applies to unimolecular fragmentation reactions and is a result of the different threshold laws for the two ionization processes. An ionization efficiency curve produced by photoionization is comparable to a first derivative of its electron-ionization counterpart.

The appearance energy (AE) is the minimum energy required to photoionize and fragment the molecule AB in the reaction shown in eqn [2] and, in the absence of any excess internal energy, can provide useful thermochemical information about the reactant and products.

However, the AE will not provide a true thermochemical value if there is any reverse activation energy (E_{rev}) associated with the decomposition. Furthermore, if the rate of fragment ion production is low for photon energies just above the threshold, there will be a kinetic shift (E_{kin}). This is the energy in excess of the thermochemical threshold, including any reverse activation energy, for the ion to be detectable by the mass spectrometer. These effects are illustrated in Figure 7.

A kinetic shift can be minimized by increasing the detection sensitivity or by trapping the dissociating precursor ion and extending the time prior to mass analysis. An additional complication will arise when there is competition with another more favourable fragmentation process. This can also cause an increase in the observed AE and is often referred to as a competitive shift.

Unless reaction [2] is carried out at 0 K, the products will not be formed at any well-defined equilibrium

thermodynamic temperature because the fragmentation is a unimolecular process with no means for the products to thermalize with their surroundings. Provided that there is no excess internal energy, the experimental AE for reaction [2] at a given temperature is given by

$$AE = \Delta H_f^0(A^+) + \Delta H_f^0(B^+) + \Delta H_f^0(e^-) - \Delta H_f^0(AB) - \Delta H_{cor} \quad [3]$$

where ΔH_{cor} is a thermal energy correction term to convert the products to the same temperature as the neutral precursor. ΔH_{cor} varies with different fragments, but is typically in the 10–30 kJ mol⁻¹ range at 298 K.

For threshold studies it is convenient to consider the ejected electron at rest at all temperatures, i.e. $\Delta H_f^0(e^-) = 0$. This stationary electron convention is most commonly used for cationic heats of formation derived from mass spectrometry experiments. However, there are many other data compilations that invoke a thermal energy convention, in which the electron has a translational energy commensurate with the reaction temperature. At 298 K this corresponds to a difference of 6.2 kJ mol⁻¹. Consequently, when using such information it is important to know which particular convention has been adopted.

Photodissociation

Sample Introduction

The precursor ions used in a photodissociation experiment are usually generated via a mass spectrometer. This minimizes complications that can arise when ion-molecule reactions occur in the ion source. The most

Figure 6 Photoionization efficiency curve for Xe⁺ showing the extensive autoionization structure above the ionization energy of 12.13 eV.

Figure 7 A unimolecular reaction involving both a reverse activation energy and a kinetic shift.

common method of initial ion production is electron ionization as this invariably produces a larger number of primary ions than either photoionization or collisional activation techniques. The ionizing electron energy is kept as low as practicable to minimize the initial internal energy of the precursor ions, which are then mass filtered before introduction into the photodissociation region of the instrument. Variation of the ionizing energy can be used to prepare ions with different internal energies and this also facilitates the determination of the electronic state(s) involved in the photoinduced transition(s). Because of space-charge effects the precursor ion concentration is considerably lower than that of a comparable beam of neutral molecules.

Light Sources

A high-intensity source of photons is required to produce detectable numbers of photofragment ions from a mass-selected ion beam. For this reason, most experiments have used a laser for the photodissociation process. Continuous lasers generally produce the highest average power outputs, with an excellent stability and a very narrow photon energy bandwidth ($\sim 10^{-5}$ eV). They may be used to pump a dye laser to produce light from the near-infrared to the visible region of the spectrum. The use of a pulsed excimer laser to pump the dye laser can extend the wavelength range to cover the 1.5–3.5 eV energy region, although this requires the use of over 20 different dye solutions. Frequency doubling and etalon bandwidth narrowing techniques can be used to further

enhance the laser performance. Accurate wavelength calibration presents a problem for high-resolution studies. One procedure used in the visible region of 1.7–2.5 eV is to simultaneously record the iodine absorption as a reference, producing calibrations to better than 10^{-6} eV. For near UV studies, optogalvanic lines provide one of the few convenient methods available.

The interaction between the photon and ion beams can be achieved by either a crossed or a coaxial configuration. The crossed arrangement produces a better definition of the interaction region and is used when absolute cross section and angular distribution measurements are required. However, a better overlap of the two beams, and hence improved sensitivity, results from an arrangement in which both beams travel in parallel along the interaction region. This also permits the use of a Doppler tuning technique to improve the photon energy resolution and to reduce the problems associated with the ion beam thermal energy.

Mass Analysers

Photodissociation experiments are usually performed with either a beam or an ion-trap mass spectrometer. The beam instrument is a tandem mass analyser in which the first stage is used to mass select a given precursor ion. This ion beam is passed through a laser interaction region and the resulting photofragments are then energy or mass analysed by a second stage. A schematic diagram of a triple-quadrupole mass spectrometer with a coaxial configuration is shown in **Figure 8**.

Figure 8 Schematic diagram of a triple-quadrupole laser-induced photodissociation mass spectrometer operated in a coaxial configuration. IS is the ion source; Q1 is the precursor ion mass filter; Q2 is the ion photodissociation region; Q3 is the photofragment ion mass filter; ID is the off-axis ion detector; PD is a photon detector; BS is a beam splitter; and IA is an iodine absorption cell.

Apart from restricting the laser–ion interaction time, fast ion beams, particularly those produced with a magnetic sector instrument, essentially restrict the lifetimes of ions that can be detected to less than 10 μ s. This is not a limitation for an ion cyclotron resonance (ICR) or quadrupole ion storage (QUISTOR) trap, where ions can be stored almost indefinitely. However, the presence of relatively high concentrations of neutral species may result in interfering ion–molecule reactions taking place in the cell. The use of an ion trap with an external ion source can help to remove these competing processes and also allow photodissociation studies of precursor ions formed by ionization techniques other than electron ionization.

Data Processing

As in threshold photoionization experiments, photofragment ion concentrations are extremely low and it is necessary to utilize signal-enhancement techniques. Although phase-sensitive detection has been used, it is more usual to employ signal-averaged pulse counting. For photodissociation with a pulsed laser, an appropriate gating system synchronized with each laser pulse can further improve the signal-to-noise ratio.

Introduction

Few, if any, analytical techniques can compete with the versatility of NMR. Accordingly the applications of NMR in plant science (Tables 1 and 2) are diverse, and they can be divided into three broad categories. First, NMR is an essential tool for the structural elucidation of the molecular components of plants. Structural investigations might involve the identification of plant metabolites, either in complex mixtures or after purification; the determination of the three-dimensional structure of soluble plant proteins; or the characterization of the insoluble matrix that makes up the plant cell wall. Second, NMR is invaluable for probing the pathways that process metabolites and thus

sustain a plant through its life cycle. Typical objectives include establishing the existence of a pathway, measuring the flux of material that it supports, and investigating the factors that influence its contribution to the overall function of the metabolic network. Finally, NMR detection of plant tissue water signals allows both direct spectroscopic analysis of the water content, including biophysical characterization of specific water fractions, and the application of NMR imaging. The latter permits the noninvasive analysis of tissue structure and root architecture, and it is especially useful for investigating the dynamics of water movement in the vascular tissues of stems and leaves. These applications of NMR in plant science are outlined here, including comments on technical considerations and the plant-specific experimental arrangements that are sometimes necessary.

Structural Elucidation of the Molecular Components of Plants

The NMR analysis of material derived from plants is essentially no different from the analysis of comparable

Table 1 Typical applications of NMR spectroscopy for plants and plant material

Nucleus	Applications
^1H	Metabolite fingerprinting and profiling of plant extracts; structural analysis of low-molecular-weight natural products and macromolecules; biophysical characterization of tissue water fractions and their response to drought, temperature stress, and other physiological perturbations; occasional use of <i>in vivo</i> ^1H NMR for metabolic analysis
^2H	^2H -labeling studies of biosynthetic pathways
^{11}B	Characterization of boric acid and borate esters <i>in vivo</i> and in tissue extracts
^{13}C	^{13}C -labeling studies of biosynthetic pathways; natural abundance and ^{13}C -labeling studies of primary metabolism <i>in vivo</i> , including analysis of the compartmentation of organic acids and amino acids; steady-state metabolic flux analysis; solid-state ^{13}C NMR analysis of cell wall material
^{14}N	<i>In vivo</i> detection of nitrate and ammonium
^{15}N	^{15}N -labeling studies of biosynthetic pathways; ^{15}N -labeling studies of primary and secondary metabolism <i>in vivo</i> ; solid-state ^{15}N analysis of dried plant material
^{19}F	^{19}F -labeling studies of biosynthetic pathways; analysis of the biodegradation of fluorinated xenobiotics; cytoplasmic and vacuolar pH measurements using fluoroalanine
^{23}Na	<i>In vivo</i> detection of intracellular sodium; characterization of cytoplasmic and vacuolar sodium pools under salt stress
^{27}Al	Characterization of aluminum complexes in species that accumulate aluminum
^{31}P	Cytoplasmic and vacuolar pH measurements; <i>in vivo</i> analysis of bioenergetics and intracellular pH regulation during physiological perturbations such as oxygen deprivation; analysis of the uptake and subcellular distribution of inorganic phosphate, phosphite, and methylphosphonate; analysis of the effect of P-starvation on P-utilization; metabolite profiling of phosphate esters in plant extracts; use of inorganic phosphate as a reporter for the uptake of paramagnetic ions
$^{35}\text{Cl}/^{37}\text{Cl}$	<i>In vivo</i> detection of the vacuolar chloride pool; potential applications in the analysis of chloride uptake and transmembrane exchange
^{39}K	<i>In vivo</i> detection of intracellular potassium: the vacuolar pool is readily detectable, but the very broad signal from the cytoplasmic pool has rarely been reported
^{113}Cd	Characterization of the ionic form of cadmium in xylem sap
^{133}Cs	<i>In vivo</i> detection of subcellular pools arising from exposure to cesium; reporter of changes in the cytoplasmic and vacuolar anionic composition

samples of nonplant origin. The nature of the samples allows the investigator to take advantage of the full range of hardware options and detection schemes available on a modern NMR spectrometer, with the usual aim of maximizing detection sensitivity and spectral resolution. This leads to several generalizations about the spectrometer configuration for structural studies.

First, it is advantageous to record spectra at the highest available field strength, since this increases the sensitivity of detection, the achievable signal-to-noise ratio, and the spectral resolution. Analysis of soluble low-molecular-weight components is usually performed with a ^1H NMR operating frequency in the range 300–600 MHz, whereas determination of the tertiary structures of macromolecules is best done in the range 600–950 MHz.

Second, the design of the detector system has a major influence on sensitivity, and this may be a critical factor if a purified metabolite or macromolecule is only available in limited quantities. Sensitivity can be increased by using (i) cryogenic probes, to reduce the thermal noise in the detection system; (ii) microprobes, to allow spectra to be recorded from much smaller volumes than conventional probes; and (iii) inverse detection probes, to allow the relatively insensitive ^{13}C and ^{15}N isotopes to be detected via the through-bond (scalar) couplings to the much more sensitive ^1H nucleus.

Third, multidimensional NMR detection schemes provide further opportunities for increasing sensitivity and spectral resolution, as well as for establishing the connections between signals that are essential for metabolite identification and macromolecular structure

determination. Some of these experiments exploit the presence of elevated levels of ^{13}C and ^{15}N in material obtained from plants cultivated in the presence of a labeled substrate. The latter might be a compound that leads to widespread labeling of the metabolic network, for example, $^{13}\text{CO}_2$ for photosynthetically active tissue or ^{13}C -labeled glucose for a heterotrophic cell suspension, or a compound that is specific for a relatively isolated pathway, for example, phenyl[1,3- $^{13}\text{C}_2$]lactic acid as a precursor for tropane alkaloid synthesis. Alternatively heterologous expression systems can be used to generate suitably labeled plant proteins for three-dimensional structure determination.

Metabolites, soluble proteins, and cell wall components are the main targets for structural analysis, but in contrast to microbial and mammalian systems, it is the identification of secondary metabolites, rather than the analysis of proteins, that dominates the structural analysis of materials of plant origin using NMR. The continuing importance of this apparently mundane activity reflects both the huge diversity of plant chemistry – the total number of metabolites utilized by the plant kingdom has been estimated to be of the order of 2×10^5 – and the likelihood of isolating novel compounds that have useful chemical properties. Structure determination exploits the magnetic interactions between neighboring NMR-detectable atoms, and usually involves implementing two-dimensional NMR methods (Figure 1) that are sensitive to scalar ^1H – ^1H interactions, for example, COSY or TOCSY, followed by methods that allow the ^1H spin systems to be correlated with the natural-abundance ^{13}C

Figure 1 Gradient-selected COSY spectrum of a perchloric acid extract of *Arabidopsis thaliana* leaves. The boxes emphasize the correlations between ^1H signals for selected metabolites: A, alanine, αCH , and βCH_3 ; B, glutamine, αCH , βCH_2 , and γCH_2 ; C, asparagine, αCH , βCH , and $\beta'\text{CH}$; D, β -D-glucose, C1H, and C2H; E, α -D-glucose, C1H, and C2H. The seedlings were incubated with [$1\text{-}^{13}\text{C}$]glucose before extraction, leading to ^{13}C -coupled satellite signals on the glucose C1H peaks. Figure courtesy of T.C.R. Williams.

atoms of the backbone, for example, HSQC, HMQC, or HMBC. This combination of experiments provides a powerful tool for correlating the proximity of the NMR-detectable atoms and hence identifying the molecular structure.

Scalar interactions cannot occur between atoms of different molecules, and so it is an inherent feature of the NMR approach to structure determination that it can be applied to relatively crude extracts. However, it would be unusual to attempt structural analysis without some purification, and the coupling of separation techniques, such as high-performance liquid chromatography (HPLC) and capillary electrophoresis, to NMR spectrometers is routine in analytical laboratories (**Figure 2**). These so-called hyphenated NMR systems can also be run in parallel with mass spectrometry (MS), either single MS or tandem MS/MS, generating data on molecular weight and fragmentation patterns to match the NMR data and creating an even more versatile tool for structure determination. The interface between the LC system and the NMR spectrometer is critical to the success of LC-NMR, and while continuous-flow operation can be informative, various stopped-flow

techniques, including loop storage and solid-phase extraction, are employed to ensure that the concentration in the NMR probe is sufficient to record the necessary spectra.

Plant cell walls provide another important target for structural analysis by NMR. Cell walls can be dismantled and the individual components analyzed separately, but there is also a specialist interest in applying solid-state NMR techniques to characterize intact cell wall preparations. The complexity and heterogeneity of an intact cell wall, which contains several types of polymer, present a severe challenge, and the implementation and interpretation of the solid-state NMR techniques is generally less routine than the solution-phase techniques that might be used to investigate soluble, or solubilized, components of the cell wall. However, relaxation time measurements can be informative, revealing regions of different mobility, and this information is useful in developing models of cell wall organization.

Soluble plant proteins can be analyzed in the same way as proteins from any other organism, but the databases reveal relatively few studies on such proteins. A survey in 2007 found that only 4% of the structures in the Protein Data Bank were plant proteins, and of these 1500 structures, only about 10% were determined by NMR. Thus, the plant proteome has been largely ignored by NMR spectroscopists, perhaps reflecting the biomedical importance of other more favored groups of organisms and/or the difficulty in purifying adequate quantities of material from a plant tissue.

Figure 2 General scheme for hyphenated NMR analysis of natural products. Numerous options exist for the solvent, column, MS detection scheme, LC-NMR interface, NMR probe, and NMR detection scheme leading to great versatility and analytical power. One option is to set the interface for continuous-flow mode, recording a series of NMR spectra as a function of elution time. Alternatively, the system can be run in stopped-flow mode, either by stopping elution with a valve or by collecting the fractions of interest in storage loops. Another option is to use solid-phase extraction to concentrate particular fractions before NMR analysis. Microcoils and cryogenic probes can be used to increase NMR sensitivity and maximize the power of the technique.

Analyzing the Plant Metabolic Network

NMR studies of the plant metabolic network depend largely on the analysis of tissue extracts, but it is also possible to take advantage of the nondestructive nature of the NMR technique to record spectra from small plants, excised tissues, and cell suspensions *in vivo*. There are several reasons why this might be useful. First, *in vivo* detection may reveal details that would be lost on extraction, for example, information about labile metabolites that are difficult to extract quantitatively or information about the subcellular compartmentation of ions and metabolites. For example *in vivo* ^{31}P NMR allows the measurement of the cytoplasmic and vacuolar pH values in plant cells, and this has been exploited in many studies, reflecting the physiological importance of pH as an effector of enzyme activities. Second, *in vivo* NMR can provide a more efficient and statistically reliable method for establishing time courses of metabolic responses to physiological perturbations than serial extraction of replicate samples. The time resolution of the *in vivo* NMR time course is determined by the sensitivity of the spectrometer and the concentration of the detected

metabolites, and the approach is particularly suitable for revealing metabolic responses to abiotic stress, since these responses often occur over a timescale of minutes or hours.

These advantages need to be set against the easier sample handling, better sensitivity, and better spectral resolution for the NMR analysis of tissue extracts. *In vivo* NMR experiments need to be performed on tissues under controlled physiological conditions, and this makes them more demanding and time-consuming. In particular, it is necessary to use an experimental arrangement that can ensure the supply of nutrients, including oxygen, and removal of waste products, within the confines of the NMR magnet (Figure 3). This objective is complicated because the direct detection of most metabolites requires the use of the same high-field magnets that are used for high-resolution NMR. Thus, *in vivo* NMR analysis of plant metabolism is usually performed in the 5, 10, 20, or 25 mm diameter probes that can be accommodated in magnets with ^1H operating frequencies in the range 300–600 MHz. This puts considerable limitations on the range of suitable samples, and most *in vivo* NMR metabolic analysis is done on excised organs, tissues, and cell suspensions rather than whole plants. A further limitation is that no satisfactory procedure has been developed for illuminating photosynthetic tissues in the NMR probe at the tissue densities that are required to obtain useful spectra. Thus metabolic *in vivo* NMR is effectively restricted to heterotrophic tissues, for example, root tissues and dark-grown cell suspensions.

Metabolic analysis is largely dependent on spectra recorded at natural abundance by ^1H and ^{13}C NMR, and from labeled extracts and tissues by ^2H , ^{13}C , and ^{15}N NMR. However, there are also applications for a range of other isotopes in characterizing the ions and metabolites of plant tissues (Table 1). Thus, ^{31}P NMR, which is mentioned earlier in the context of intracellular pH determination, is also used extensively for characterizing phosphate esters and inorganic phosphate, whereas ^{14}N NMR is useful for characterizing the utilization of the two important inorganic nitrogen sources for plants: nitrate and ammonium. ^{23}Na , ^{27}Al , ^{39}K , ^{113}Cd , and ^{133}Cs NMR have all been used to characterize metal ion pools or metal ion complexes in plants. ^{113}Cs NMR has also been used as an indirect sensor of changes in the cytoplasmic nitrate pool. Other isotopes, including ^{11}B , ^{19}F , ^{35}Cl , and ^{37}Cl , find occasional use, and in this group, ^{19}F NMR has an emerging role in biosynthetic studies. Finally, labels can also be detected indirectly, through the effect of the label on the NMR properties of a neighboring atom, as in the detection of ^2H - and ^{18}O -induced isotope shifts in ^{13}C NMR spectra.

The main options for probing plant metabolism with NMR are as follows: (i) quantification of ions and metabolites, either *in vivo* or in tissue extracts; (ii) metabolite

Figure 3 Experimental arrangement for recording *in vivo* NMR spectra from a plant cell suspension. A, pump for outlet tube; B, pump for inlet tube; C, oxygen line; D, reservoir for the suspending medium; E, overflow tube attached to a water pump; F, screw cap 10 mm diameter NMR tube; G, outlet tube; H, inlet tube; I, Vyon[®] porous plastic support; J, packed cell suspension; K, Vyon porous plastic support. In this system, the tissue sample is maintained in a defined physiological state by circulating an oxygenated medium between the reservoir and the NMR tube. Freshly oxygenated medium is pumped into the NMR tube, and is then drawn down through the sample and the porous filter at the base of the tube under the influence of the suction created by the pump on the outlet line. Placing the inlet tube just below the surface of the reservoir, and running the inlet flow slightly faster than the outlet flow, ensures that the liquid level in the NMR tube remains constant, but the arrangement also includes a backup overflow system to prevent flooding in the event of a pump failure. Numerous other designs of circulation system have been used for *in vivo* NMR studies of plant tissues, and it is also possible to construct aeration systems based on the airlift principle. Figure courtesy of T.C.R. Williams.

fingerprinting and profiling of plant extracts; (iii) biosynthetic studies, using stable isotope labeling and subsequent NMR analysis either *in vivo* or in extracts; (iv) metabolic flux analysis, based on either transient or steady-state stable isotope labeling; and (v) testing hypotheses about the integration and regulation of metabolism by measuring metabolic responses to changed

circumstances. Each of these topics is outlined here, with comments on the scope of the approach and the status of the NMR method relative to other techniques.

Quantifying ions and metabolites is a natural extension of the central role that NMR plays in the structural elucidation of plant metabolites. NMR spectroscopy is an inherently quantitative technique provided precautions are taken to record spectra under conditions where the signal intensities can be interpreted quantitatively, for example, under fully relaxed conditions or with knowledge of the relevant saturation factors. Moreover, the high stability of modern NMR spectrometers guarantees highly reproducible spectra and permits the quantification of a metabolite even if its identity is unknown and/or no standard sample is available. This versatility is not always appreciated, and it is not uncommon to find the implementation of rather elaborate enzyme-based assays under circumstances in which a relatively trivial NMR measurement would suffice. *In vivo* NMR signals can also be quantified, leading to tissue concentrations on a fresh weight or tissue volume basis, and in principle, a direct comparison between tissue and extract spectra can provide information on the effectiveness of different extraction techniques, although this option for validating extraction methods is rarely implemented.

Metabolite fingerprinting and metabolite profiling are techniques for comparing the metabolite composition of cells and tissues. The aim is to conduct a rapid, unbiased, and comprehensive analysis of metabolite composition, most commonly by ^1H NMR, MS, or infrared spectroscopy. Fingerprinting and profiling exploit the wealth of metabolic information in the ^1H NMR spectra of tissues extracts for these metabolomic analysis in different ways. In fingerprinting (Figure 4), a statistical analyses of the unassigned ^1H NMR spectra of unfractionated extracts is used to compare the overall metabolic composition of related samples and to identify regions of the spectrum that discriminate between the samples, whereas in profiling, the aim is to assign as many signals as possible, and thus to identify and quantify a subset of the metabolome, before making comparisons between related samples. NMR is a fast and convenient tool for fingerprinting, but it is less effective than MS for profiling, because the substantially greater sensitivity of MS leads to the identification of a greater number of metabolites. Both techniques lead to the definition of a so-called metabolic phenotype for the sample and allow hypotheses about the metabolic equivalence of related samples to be tested.

Typical applications of metabolite fingerprinting in plant science include (i) authentication and quality control of food products and traditional medicines; (ii) analysis of the substantial equivalence of wild-type, mutant, and transgenic plants; and (iii) analysis of the impact of growth conditions and other physiological

perturbations on metabolite composition. The second application is particularly important in the areas of functional genomics and systems biology, since establishing that there is a metabolic difference between genotypes can lead to predictions about the sites of action of genes in the metabolic network. The adoption of metabolomic analysis by NMR and other techniques as a research tool in plant science has triggered a flood of papers, reflecting the value of the approach and the recognition that knowledge of genomes, transcriptomes, and proteomes does not necessarily lead to an understanding of the metabolic performance.

The next major metabolic application of NMR in plant science is pathway delineation – establishing the identity of the pathways that interconvert metabolites. In some instances, this may involve establishing whether a pathway that is generally considered to be present in plant cells is actually present in a particular species or cell type, but more commonly, it involves establishing the biosynthetic route to a secondary metabolite. Stable isotope labeling, typically with ^2H -, ^{13}C -, or ^{15}N -labeled precursors, is the key to solving this problem, and while MS can readily identify the number of labeled atoms in a molecule, NMR is a more powerful technique for establishing their specific location. In the classical approach, precursor–product relationships are established by supplying a specifically labeled precursor that is thought to be an intermediate in the pathway and measuring the labeling of the putative product (Figure 5). This approach has the advantage of simplicity, provided suitably labeled precursors can be synthesized, and it is widely used. An alternative is to use a retrobiosynthetic approach in which the tissue is first labeled with a precursor of central metabolism, for example, $^{13}\text{CO}_2$ or $[\text{U-}^{13}\text{C}_6]\text{glucose}$, and then the redistribution of label into polymeric end products of metabolism, for example, starch or protein, is used to deduce the labeling pattern of the intermediates of central metabolism. These labeling patterns can then be used to predict the labeling of secondary metabolites derived from central carbon metabolism and hence to test hypotheses about the contribution of particular biosynthetic pathways. The retrobiosynthetic approach requires a more extensive analysis of the redistribution of the label than precursor–product analysis, but it takes advantage of readily available labeled precursors and it can also provide quantitative estimates of the importance of competing pathways in some circumstances.

Stable isotope labeling is also the key to measuring the rate at which metabolites are transformed by the metabolic network. In one approach, steady-state flux analysis, the redistribution of label is analyzed under conditions that correspond to a metabolic and isotopic steady state, and a flux map is deduced that can be superimposed on the metabolic network (Figure 6). Typically this approach

Figure 4 Metabolite fingerprinting of developing sunflower embryos. (a) Representative 600 MHz ^1H NMR spectrum of a perchloric acid extract of sunflower embryos harvested 15 days after flowering (DAF). The sample was dissolved in D_2O , and the spectrum was recorded with presaturation to suppress the residual water peak. The spectrum includes signals from amino acids, carbohydrates, organic acids, and aromatic compounds, with the carbohydrate signals dominating the central region of the spectrum. (b) Score plot showing the first three components of a principal component (PC) analysis of the ^1H NMR spectra recorded from 77 extracts of sunflower embryos at different stages of development. Spectral intensities were binned at a resolution of 0.01 ppm and scaled to a constant total spectral area; bin values across samples were then mean normalized and scaled to unit variance. The scores group according to developmental stage along the PC1 axis: ●, 10 DAF; ●, 15 DAF; ●, 20 DAF; ●, 25 DAF; ●, 28 DAF; ●, 30 DAF. Figure courtesy of N.J. Kruger.

allows the measurement of multiple net and exchange fluxes in central metabolism, and thus provides a quantitative description of the metabolic activity that is ultimately essential for cell function. In a second approach, known as dynamic, transient, or instationary flux analysis, measurements of the time course of the redistribution of label, coupled with measurements of the concentrations of the metabolites, are used to determine fluxes. This

approach is more readily applied to pathways at the periphery of the metabolic network, and in plants, it is mainly used to characterize some of the relatively isolated pathways of secondary metabolism. NMR analysis makes a major contribution to steady-state analysis in both plants and other organisms, reflecting the importance of positional labeling information in deducing the fluxes, but it is less commonly used for transient flux analysis, because

Figure 5 Metabolism of $[1-^{13}\text{C}]$ glucose by mitochondria isolated from a heterotrophic *A. thaliana* cell suspension. These mitochondria have a fully functional glycolytic pathway associated with the outer membrane, and the operation of the pathway, including the channeling of metabolites, can be investigated directly by NMR. Here ^1H -decoupled ^{13}C NMR spectra were recorded at 150.9 MHz during a labeling experiment after (a) 1 h; (b) 6 h; and (c) 12 h. Peak assignments: 1, β -D-glucose 6-phosphate, C1; 2, β -D-glucose, C1; 3, β -D-fructose 6-phosphate, C1; 4, dihydroxyacetone 3-phosphate, C3. The mitochondrial density is very low, and the signals are derived from metabolites in the suspending medium. Figure courtesy of J.W.A. Graham.

defining the time courses with the necessary precision often demands the high sensitivity of MS.

All of the metabolic NMR approaches described earlier can be used to investigate the metabolic response of plants to abiotic, genetic, and physiological perturbations, with the aim of testing hypotheses about the integration and regulation of plant metabolism. Metabolic responses will usually take the form of changes in metabolite levels and/or changes in metabolic fluxes, and NMR-based metabolic analysis is an effective way of investigating these effects. These investigations may be targeted on particular steps or metabolites, or system-wide, taking advantage of the wealth of data that can be obtained across the network using metabolomics or network flux analysis. It may also be relevant in these studies to characterize the intracellular environment, using the information on subcellular compartmentation and intracellular pH that can be obtained from *in vivo* NMR spectroscopy. For example, changes in pH occur in response to a wide range of abiotic stresses, such as anaerobiosis or osmotic shock, and these changes can influence metabolite levels and metabolic fluxes via the pH-dependence of enzyme activities. Although targeted analyses can be informative, greater emphasis is currently placed on system-wide analyses in plant research, for example, using flux analysis to investigate the robustness

of the plant metabolic network or using metabolomics to analyze the variability of the metabolome under controlled growth conditions. NMR and MS provide complementary approaches to solving these questions, and in flux analysis in particular, there are good reasons for using both techniques in parallel, although this has rarely been done and reported.

Plant Tissue Water and NMR Imaging

The abundance of water in most tissues, together with the ease with which ^1H NMR signals can usually be detected, has two important consequences for applications based on the NMR detection of water. First, tissue water NMR signals can be detected at low magnetic field strengths, allowing a much greater range of measurement configurations than are possible in a conventional high-field, narrow-bore superconducting magnet; and second, the strength of the signal allows it to be fragmented by field gradients into a set of spatially resolved signals that can be reconstructed to generate NMR images (Figure 7). Separately and in combination, these technical considerations allow NMR spectroscopists to conduct physiologically relevant experiments on water content and water movement in intact plants (Table 2).

Figure 6 Steady-state metabolic flux analysis of central carbon metabolism in a heterotrophic *A. thaliana* cell suspension. The cells were incubated for 5 days with $[1-^{13}\text{C}]$ glucose, and then the redistribution of the label was quantified by NMR analysis of the soluble metabolites in a perchloric acid extract. Starch and protein were recovered from the insoluble fraction, and the labeling of these components was analyzed after hydrolysis. The label information, together with data on glucose uptake and biomass production, was used to generate a flux map by a numerical fit to an overdetermined model. Flux values are expressed in μmol per day per flask. Single values correspond to fluxes in the direction of the arrow; single values with asterisks correspond to net fluxes for reversible steps with a high degree of reversibility; double values correspond to the forward and reverse fluxes for other reversible steps. Figure courtesy of T.C.R. Williams.

Plant–water relations are very sensitive to disturbance and stress, making it essential to study the dynamic properties of water in plants under realistic conditions. This may mean making measurements in the field, in glasshouses, or in controlled-environment chambers where factors such as atmospheric composition, humidity, light intensity, and temperature can be defined. It is also desirable to be able to work with plants of agricultural and horticultural importance, since stresses that have negative effects on plant productivity often disturb plant cell water balance. It is possible to make considerable progress toward achieving these objectives using permanent magnets and open-access electromagnets. The utility of portable magnets for nonspatially resolved measurements of water content and xylem flow has been demonstrated outside the laboratory, and efforts

are underway to develop truly portable spectrometers that would not be compromised by excessive weight or power consumption. The development of the NMR-MOUSE[®], a combined low-field permanent magnet and sensor system, offers increased portability for *in situ* applications, and its small size allows the ^1H NMR signal to be detected from any relevant part of the stem of a plant.

Portability is not such a significant consideration for laboratory experiments and it is the scope for making measurements on plants under well-defined physiological conditions that is the most important factor. Electromagnets with open access between the pole pieces can be combined relatively easily with controlled-environment arrangements, permitting measurements of tissue water under both spatially resolved and

nonspatially resolved conditions. For example, in a system of this kind operating at 0.72 T, a magnetic field strength well below the absolute minimum that would be considered for high-resolution NMR spectroscopy, it is possible to quantify water flow through the xylem and phloem vessels in the stems of pot-grown plants, and

hence to investigate factors that alter the flow rates, such as the time of day.

Achieving such good control of the environmental conditions in higher field strength magnets is more difficult. The 3 T imaging system at the Wageningen NMR Centre in The Netherlands is currently the only system that allows measurements on large plants and small trees under controlled environmental conditions (Figure 8). In contrast to clinical imaging systems, this magnet has a vertical bore, allowing measurements to be made without disturbing the natural orientation of the plant. Imaging at higher field strengths is restricted to much smaller samples, such as seeds and germinating seedlings. Here the emphasis is often placed on achieving the highest spatial resolution – an in-plane resolution of $20 \times 20 \mu\text{m}$ with a slice thickness of $50 \mu\text{m}$ can typically be achieved at 9.4 T (400 MHz) – with the aim of observing anatomical features that might be lost or distorted in conventional microscopy. It also becomes possible at the highest field strengths to image components other than water, such as lipid in oil storage tissues, or abundant carbohydrates and amino acids in the hypocotyls of germinating castor bean seedlings, or the distribution of sodium in salt-stressed tissues. Images have also been reported of metabolites labeled with ^{13}C or ^{19}F , but these experiments are far from routine and their usefulness is difficult to judge.

Despite these possibilities, it is the work on water content and water transport that provides the most compelling argument for plant NMR imaging. This work has a firm theoretical foundation, based on extensive analysis of the relaxation properties of plant tissue water fractions and an appreciation of the complicating effects of the intercellular air spaces that are found in many plant tissues. Moreover, flow imaging provides direct access to fundamental physiological processes that have

Table 2 Typical applications of NMR imaging for plants

Measurement	Applications
Anatomical	High resolution imaging of plant structures, for example, the vascular tissues in roots and stems, ripening fruits, and germinating seeds Definition of root architecture in soil or artificial substrates
Analytical	Determination of spatially resolved water content from spin density images Determination of spatially resolved lipid content in oil-storing seeds and tissues Determination of abundant metabolites, for example, sucrose or glutamine Determination of spatially resolved Na content in plants exposed to salt stress
Dynamic	Analysis of spatially resolved NMR relaxation times and diffusion coefficients for tissue water Determination of cell size and water permeability from diffusion coefficients Determination of bulk water flow through the xylem and phloem Direct observation of the uptake and translocation of $^2\text{H}_2\text{O}$ and ^{13}C -labeled sucrose Direct observation of the uptake and translocation of paramagnetic relaxation agents

Figure 7 NMR images of the stem of a *Ligustrum japonicum* tree. The stem diameter is approximately 7 cm, and the images were recorded using the 3T imaging system at the Wageningen NMR Centre. The contrast in the three images, from left to right, is based on water content, the spin–spin relaxation rate, and the spin–spin relaxation time, respectively. The small disc arises from a tube of water included for calibration purposes, and the scale bars emphasize the inherently quantitative nature of the measurements. The images contain a wealth of anatomical detail that can be related to known features of the stem, including the vascular tissues. Figure courtesy of H. Van As.

Figure 8 A *L. japonicum* tree positioned beneath the 50 cm diameter bore of the 3T NMR imaging system at the Wageningen NMR Centre. Gradient coils can be assembled around the trunk of the tree prior to positioning the plant in the bore of the magnet. Climate control allows imaging to be conducted under physiologically relevant conditions, and processing of the NMR images yields information about both water content and water transport through the vascular tissues. Figure courtesy of H. Van As.

been very difficult to study by other means at the necessary level of spatial resolution. However, owing to the specialized expertise and equipment that it requires, plant NMR imaging is only performed in a small number of laboratories despite its undoubted potential to address important problems.

Conclusion

Plant science makes use of NMR techniques that range from the simplest form of spectroscopy through to the most advanced imaging experiments. Similarly, the applications themselves range from routine analyses that are performed in many laboratories, for example, the structural elucidation of secondary metabolites, through to such demanding and nonroutine applications as network flux analysis or the measurement of phloem water transport. The continuing development of the NMR method itself, coupled with the central importance of

much of the data that is currently being generated by NMR in the fields of structural analysis, metabolism, and plant–water relations, suggests that plant scientists will continue to draw on the expertise of NMR spectroscopists for many years to come.

Plasma Desorption Ionization Using ^{252}Cf in Mass Spectrometry

Californium-252 is the key ingredient in a mass spectrometric method known as ^{252}Cf -plasma desorption (^{252}Cf -PD). The ^{252}Cf prefix to 'plasma' distinguishes this method from other mass spectrometric methods that also use a plasma to generate ions. The method uses the energy released in nuclear fission to produce mass spectra of a wide variety of materials ranging from refractory inorganic matrices to samples of biological materials.

A high-energy fission fragment from the spontaneous nuclear fission of ^{252}Cf , penetrating a sample of insulin, penicillin or an unknown protein, decomposes most of what is in its path, but occasionally, an intact molecular ion of the sample is ejected from the surface of the fission track into the vacuum of a mass spectrometer where its molecular mass is measured. This article outlines the essential features of the method including the nuclear properties of ^{252}Cf , the interaction of fission fragments with solids, ion emission from fission tracks in solids, the design of the mass spectrometer, sample preparation, and how data are acquired. Some applications have been selected that have utilized some of the unique features of the method.

A Brief History

The development of mass spectrometry for the study of molecules of biological origin did not progress until the problem of forming intact gas phase molecular ions was solved. Volatilization of the molecules by heating led to decomposition. Field desorption ionization introduced in the late 1960s was the first solution to the volatilization–decomposition problem. The discovery of the ^{252}Cf -PD method in the 1970s expanded the spectrum of molecules that could be studied by mass spectrometry. One of the first applications was determining the molecular mass of pharmaceuticals and natural products. The structures of these species were determined by a combination of other spectroscopic techniques, and the molecular mass of the intact molecule was used to verify the atomic composition of the structure that was deduced. In several cases, the molecular mass did not correlate with the proposed structure and a re-examination of the data from the other spectroscopic measurements led to the final structure. Some of the pharmaceuticals currently in use had their molecular masses first determined by ^{252}Cf -PD. These include vancomycin, amphotericin, thiothrepton,

and bleomycin, and the marine toxins, palytoxin, tetrodotoxin and the red-tide toxin.

With the introduction of fast-atom bombardment (FAB) in 1982, and matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization (ESI), most of the biomedical applications have been directed towards these methods. The ^{252}Cf -PD method has been found to have wide applicability, including the study of refractory materials, catalysts, semiconductors and frozen gases. Electronics capable of measuring the timing of events with subnanosecond resolution (the time it takes for a single photon to travel 1 cm) is used by this method as well as event-by-event data acquisition using the computer to make decisions at the molecular level, the basis of correlation mass spectrometry, a unique feature of ^{252}Cf -PD.

Properties of Californium-252

Radioactive Decay Properties

Californium-252 is produced in a high-flux nuclear reactor by multiple neutron capture from ^{239}Pu . It has a half-life of 2.6 years and decays by alpha-particle emission (97%) and spontaneous fission. In the fission process, two high-energy ions (fission fragments) are emitted in opposite directions (180°). (This feature of fission is utilized in the mass spectrometer.) Most of the energy released in the fission process appears in the kinetic energy of the fission fragments, 90–130 million electron volts (MeV). The high kinetic energy coupled with a high charge (15–25 times the electron charge) is responsible for what happens when a fission fragment interacts with a solid. An example of one of the more abundant fission fragments is the technetium ion with a kinetic energy of 100 MeV and charge of $+20$.

The Californium-252 Source

Sources of ^{252}Cf specifically designed for ^{252}Cf -PD applications are commercially available. A carrier-free sample of ^{252}Cf is electroplated onto a thin nickel foil in the form of a small circular spot with a diameter of 3 mm and is then sealed with a thin nickel foil to contain the ^{252}Cf . (Fission fragment tracks formed in the source eject ^{252}Cf atoms from the source; a process called self-transfer.) A source used in ^{252}Cf -PD contains about

$0.5\text{ }\mu\text{g}$ of ^{252}Cf and, when located to within a few millimetres of a sample, will deliver 2000–3000 fission fragments into the sample per second. The useful life of the source in a ^{252}Cf -PD mass spectrometer is of the order of 4 years.

Properties of the Fission Track

In a ^{252}Cf -PD measurement, fission fragments form a fission track in the sample to be analysed. The range of the fission fragment is of the order of $10\text{ }\mu\text{m}$. If the sample is thinner, the fission fragment passes through the sample depositing 100 eV nm^{-1} of energy in the form of electron excitation and ionization. **Figure 1** depicts the time evolution of the fission track for a 100 MeV Tc ion passing through a thin film and emerging with an energy of 70 MeV . Positive ions and electrons are formed creating a cylindrical high-temperature plasma that lasts for 10^{-15} s . If the material is a conductor, the electrons and positive ions (holes) recombine as shown on the right side of

Figure 1 and the energy is dissipated as heat. In the initial stages of the track development, atomic and molecular ions and photons are ejected from both ends of the fission track. After a period of a few nanoseconds, the track region returns to close to its original state with some evidence of dislocation of some of the atoms in the matrix.

If the matrix is an insulating material, the evolution of the fission track follows a different course. The electrons ejected from the fission track in the primary ionization are much less mobile and, as a result, the cylinder of positive charge expands due to Coulomb repulsion resulting in the development of a pressure pulse that propagates to the ends of the fission track. The high-pressure gradient generated at the surface of the sample results in ablation of material from the surface, leaving a crater approximately 20 nm in diameter and 10 nm deep. These craters have been studied in detail by scanning tunnelling microscopy. In the ^{252}Cf -PD measurement, the molecules to be analysed are located on the surface of the matrix, and those that are located close to the fission

Figure 1 Time evolution of a fission track in an insulator and conductor. A typical PD MS experiment will have an insulator as the energy deposition medium. Protonated molecules from a biological matrix are probably formed during the last stage when material ablation from the surface takes place. The craters depicted here have been observed using scanning tunnelling microscopy.

track will be desorbed from the surface within a few trillionths (10^{-12}) of a second after the fission fragment passed through the sample. A permanent damage track is formed in the insulating matrix that is chemically reactive and can be etched to increase the size of the track for microscopic analysis. It is not known when in the sequence of events species are ejected that are detected that contribute to the mass spectrum. For penicillin, 1500 neutral molecules, on average, are ejected from a single fission track and, typically, 1 track in 10 produces an intact penicillin molecular ion.

Subnanosecond Chemistry and the Fission Track

Ions that are formed as a result of excitation of the sample by fission fragments are detected in the ^{252}Cf -PD measurement. They are formed in various stages of the evolution of the fission track, from the surface, and in the gas phase immediately above the surface (called the selvedge region). The high density of ejected species close to the surface supports gas phase chemical reactions and the ejected clusters of molecules in an excited state are also a source of ions that comprise the mass spectrum. **Figure 2** summarizes the processes that can occur leading to the formation of gas phase ions from a perspective that depicts the surface region around the track. The primary fission track with a diameter of 0.1 nm is at

the centre of the track. Emanating from the track is the region excited by secondary electrons extending to 6 nm diameter. The range of vaporization extends to 20 nm.

It is likely that the species contributing to the formation of molecular ions of penicillin or insulin are located in the peripheral regions of the fission track. The molecular ions that are detected include radical cations and anions of redox species such as chlorophyll, protonated and deprotonated molecules such as in the case of insulin, and cations formed from the addition of Na ions to the molecule. The mechanism of the formation of these molecular ions is an open question. There is strong evidence that the important molecular-ion-producing chemistry is taking place in the gas phase, in the selvedge region.

Spectrum Measurement

Sample Preparation

Most of the molecules of the species to be analysed (analyte) that contribute to the mass spectrum are located in the surface region of the sample. By using adsorption at a solution–solid interface, a uniform layer of the analyte molecules can be made on the surface of a substrate. The substrate is chosen depending on the affinity of the analyte. For example, nitrocellulose is an effective matrix for adsorbing proteins from solution. Hydrophobic substrates, and cationic and anionic substrates have also been used. The sequence for sample preparation is outlined in **Figure 3**.

Figure 2 Depiction of the surface of a nascent fission track showing the various modes of ionization processes taking place based on the nature of the gas phase ions observed using different matrices.

Figure 3 The steps involved in the preparation of a sample for PD MS analysis. A matrix with a high adsorption affinity for the analyte is first deposited on the surface of a thin support film. A solution containing the analyte is deposited on the matrix layer and analyte molecules are adsorbed on the surface. The solution is then removed and the matrix–analyte layer washed to remove impurities. Reproduced from Macfarlane RD (1988) *Trends in Analytical Chemistry* 7(5): 179–183 with permission from Elsevier Science.

A thin metallized polymer film is stretched over a sample holder providing mechanical support for the sample to be analysed. (In the ^{252}Cf -PD measurement, the conducting layer is used to establish an electric field for accelerating the ejected ions into the mass spectrometer.) The adsorbing substrate is then deposited as a thin layer on the metallized surface. If nitrocellulose is used, it is electrosprayed from an acetone solution onto the surface. A solution of the analyte is then deposited onto the adsorbing layer. The solution is then removed, and the adsorbed layer is washed to remove species that do not adsorb to the surface. The sample is then mounted into the mass spectrometer and analysed.

The Mass Spectrometer

The arrangement of ^{252}Cf source and sample foil in the mass spectrometer is shown in **Figure 4**. The sample is positioned 4 mm in front of the ^{252}Cf source and behind a high-transmission metal grid at ground potential. In high vacuum, a voltage is then applied to the sample foil. When a fission fragment from the ^{252}Cf source passes through the sample foil ions are ejected from the surface of the sample foil and are accelerated through the grid with the same energy to charge ratio into a 1 m long tube called the flight tube. An ion detector, located at the end of the flight tube, generates an electronic pulse every time an ion hits the detector.

The mass of an ion is determined by measuring how long it takes for the ion to travel the distance through the flight tube to the detector, since all ions have been accelerated through a common electric field and have the same energy. (Some ions, particularly protein molecular ions, are multiply charged. In these cases, mass to charge ratio is measured and the energy of the accelerated ion is

the voltage + charge product.) The travel time is referred to as the time-of-flight (TOF). To measure the TOF of an ion, a 'time zero' marker must be generated. The complementary fission fragment, the companion of the fission fragment passing through the sample foil, provides this marker. Travelling in the opposite direction, it is detected by an ion detector located behind the ^{252}Cf source that first identifies it as a fission fragment and not an alpha-particle by the amplitude of the electronic pulse that is generated, and then sends a timing pulse to an electronic module called a time interval digitizer. For the fission track depicted in **Figure 4**, five ions were ejected from an adsorbed layer of insulin molecules. This particular track, which released a protonated insulin molecule, two fragment ions from the β -chain, a sodium ion and a hydrogen ion were identified as contributors to the mass spectrum of the insulin sample under study. For illustration, what happens to the data generated by these five ions as the analysis passes into the data acquisition phase, is followed in the subsequent sections.

Time-of-Flight Measurement and Spectrum

The time interval digitizer (TID) is a fast electronic clock that has a resolution of 80 ps. The electronic pulse from the fission detector travels to the fast clock through a wire at the speed of light and arrives at the TID while the ions are still travelling down the flight tube. The hydrogen ion arrives first at the ion detector at the end of the flight tube because it has the lowest mass and highest velocity. The electronic signal generated by this ion is sent to the TID which records the time lapsed since the arrival of the time-zero marker from the fission fragment. In this particular case, the lapsed time was determined to be 977.260 ns as shown in **Figure 5**. The clock keeps running and as the other three ions arrive, their flight times are also recorded in the same data set. After the maximum time has lapsed, the clock is reset for the next event and the data set is sent to an interrogation module, an interface between the clock and a computer, for the initial procession step. This scenario is repeated 2000 times a second as 2000 fission fragments pass through random sites in the insulin monolayer, generating the ions whose TOF values will comprise the mass spectrum for this sample.

Event-by-Event Analysis

The interrogation module is the link between experimentalist and the computer. It can be programmed to provide a variety of functions. Some of these options are indicated in the flow chart shown in **Figure 6**. The first option is the sorting of those ions used in obtaining a mass calibration, converting TOF values into m/z values. In the experiment used in the illustration, a decision was made to use the sodium and hydrogen ions as calibration ions, and it

Figure 4 The geometrical arrangement of the essential components of a PD MS system. In the event portrayed here, five ions were ejected from the fission track. Subsequent measurement and processing of the data for these five ions are illustrated in **Figures 5, 6 and 7**.

Figure 5 Conversion of ion detection into electronic pulses that are transmitted to a fast clock. The measured time-of-flight for the five ions displayed at the digitizer output is then transferred to a computer for processing.

was determined by previous measurements that the TOF values for these ions were in time windows of 980 ± 10 ns and 1880 ± 10 ns respectively. TOF values were stored 'as is' as a separate file. Counting the number of ions detected for a particular event, truncation of the significant figures for a TOF value, and detecting whether particular sets of species of ions are formed in the same event are some of the options that have been used in ^{252}Cf -PD studies.

Examining the ions formed from a single fission track and interacting with the data set at the molecular level is a unique feature of the ^{252}Cf -PD method.

Generating a Mass Spectrum

What comes out of the interrogation interface is stored in a computer. For the insulin measurement being used for

Figure 6 Features of event-by-event analysis. The data from the digitizer are sorted according to the objective of the experiment. A standard PD MS analysis involves identifying the calibration ions and storing the data with 78 ps resolution. The data for other ions are truncated to 1 ns resolution and stored. Examples of other software-controlled options are also listed.

illustration, the TOF values for the calibration ions are identified by the interrogation module and stored in a separate computer file which sorts by TOF value and records the frequency distributions of TOF values. All other TOF values are truncated to 1 ns resolution and stored in a file that will be used to generate the mass spectrum over the recorded mass range. The sequence of events is depicted in **Figure 7**.

The TOF spectrum is a composite of contributions from 10^6 to 10×10^6 fission fragments passing through the sample foil in a typical measurement requiring 10–100 min of running time. After the measurement is completed, the accumulated TOF spectra for the calibration ions are displayed as shown in **Figure 7** and the mean TOF values are determined. A calibration equation is calculated using the known masses of the calibration ions. The accumulated TOF spectrum for the range of TOF values set for the time interval digitizer (e.g. 32 μs) is then processed. A portion of the TOF spectrum is shown in the lowest block in **Figure 7**. Peaks in the spectrum are identified, and mean TOF values for each peak determined. These TOF values are converted into m/z ratios and are tabulated. From this analysis, it was determined that ion number 5 depicted in **Figure 4** was from a protonated insulin molecule, and ion numbers 3 and 4 were fragment ions from the β -chain of a neighbouring insulin molecule close enough to be ejected by the same fission track. It is possible that the two insulin molecules were ejected from the surface as part of a cluster of molecules and, in the region just above the surface, processes took place within the cluster resulting in the formation of the protonated insulin molecule with the

protonated second insulin ion acquiring enough internal excitation to dissociate into a protonated fragment of the β -chain and, presumably, a neutral fragment of the α -chain. The formation of these two ions from the same fission track is an example of a correlation phenomenon and is the consequence of two insulin molecules being within nanometres of each other on the surface of the matrix.

Characteristics of a Mass Spectrum

Common Features for all Matrices

Although ions from the fission track are emitted from both ends, generally only the ions emitted from one end are used to produce a mass spectrum. Some of the ions emitted are not structurally related to the sample molecules being studied but are to high-energy processes that are characteristic of a high-temperature plasma. These ions include H^+ , the dominant ion in the spectrum, H_2^+ , H_3^+ , electrons, H^- , and a set of positive and negative hydrocarbon ions in the m/z range 12–100. These ions originate from impurity molecules on the surface of the sample and are formed in high-energy gas phase processes near the surface.

Involatile Organic Samples

Most of the studies carried out for organic samples have involved involatile, highly polar biological molecules because this class of compound was not generally amenable to mass analysis prior to the development of

Figure 7 Example of the ion sorting process. The software has identified ions 1 and 2 in the event depicted in **Figure 4** as H^+ and Na^+ calibration ions and has stored these data in separate files. It then truncates the TOF values for all five ions and stores these data in a separate file that will be used to generate the full mass spectrum. This process is repeated 2000 times per second over a period of a few hours. The mass spectrum is a composite of the accumulation of the ions emitted from 10^6 to 10×10^6 fission tracks.

^{252}Cf -PD. Peptides, proteins, synthetic oligonucleotides are some of the classes of compound that were characterized by this method. These compounds produce protonated molecules and ions formed by alkali metal ion attachment to the molecule. In addition, many of these species form deprotonated negative molecular ions as well. By measuring the m/z values of these species, the M_r of the parent molecule can be identified. In addition to the protonated molecule, an extensive pattern of fragment ions is also formed due to the dissociation of ions that have acquired a high level of internal excitation in the desorption/ionization process. This feature of ^{252}Cf -PD, the identification of M_r and acquisition of an extensive high-excitation fragmentation pattern in a single measurement, is unique amongst the desorption/ionization mass spectrometric methods.

Involatile Inorganic Species

The ^{252}Cf -PD mass spectrum of metal halides and oxides consists of a family of cluster ions of these compounds

extending to over m/z 10 000, produced by the ejection of small domains of the crystal lattice in the region around the fission track. In addition, cluster ions are also observed that do not correlate with the composition of the crystal lattice, indicating that some of the cluster ions are involved in gas phase reactions in the desorption plume. One of the unique applications of ^{252}Cf -PD is the elucidation of the composition of large transition metal cluster compounds with M_r values approaching 10^5 .

Correlations and Ion Multiplicity

While most of the ^{252}Cf -PD measurements have involved the recording of mass spectra, a higher level analysis is made possible by the event-by-event feature of the data acquisition, as described above. In this section, two examples are given that make use of this feature. The evolution of the fission track and the processes leading to ion formation are complex and variable. Each fission track is unique. Some tracks generate a large number of

ions while others produce none. The generation of a protonated insulin molecule is a rare event, observed in one in a hundred fission tracks. To learn more about those tracks which produce this ion, the interrogation module can be programmed to determine how many other ions are formed in the event that produced the protonated insulin molecule. This experiment is outlined in Figure 8.

A time window is set up in the interrogation module encompassing the TOF values for the protonated insulin molecule. The data file formed for each event is interrogated to determine the number of ions detected. Two scenarios are portrayed, one in which four ions are

detected but none with the TOF of insulin. The multiplicity of this event (4) is stored in a data file. In the second event, 10 ions were detected, and one was within the TOF window of insulin. The multiplicity of this event was then stored in a separate data file. After 10^6 fission fragments had passed through the sample, two multiplicity histograms were generated; the blocks shown in Figure 8. By recording data at the event-by-event level, it was possible to determine that some fission tracks evolve in a manner that enhances the ion emission probability and these tracks have a greater probability for generating the large protonated insulin molecule.

Figure 8 Example of a correlation measurement. The experiment was to determine how many ions are emitted from a fission track that produces a protonated insulin molecule. The interrogation module was programmed to count the number of ions detected for each event where an insulin molecular ion was detected, and store that sum in a separate file. The ion multiplicity for all other events was then stored in a separate file. The conclusion of this study was that tracks that desorb large molecular ions also desorb a much larger number of other ions than average. Other types of correlation measurements include sorting events where one or two ions of a particular type are emitted from the same track.

^{252}Cf -PD as a Microprobe for Heterogeneity at the Nanometre Level Using Correlation Analysis

Most of the samples that have been studied by ^{252}Cf -PD have been chemically homogeneous, pure samples of a biological molecule or inorganic matrix. Under these circumstances, if two or more ions are detected in a single fission fragment event, desorption/ionization is correlated because they were formed from the same desorption plume. The plume contains approximately 1500 identical molecules that were in close proximity in the sample matrix and within the excitation volume of the fission track. However, if the sample is not chemically homogeneous, microscopic heterogeneity at the nanometre level can be measured by studying the composition of the desorption plume at the event-by-event level. If the sample consists of two components that are homogeneous at the nanometre level, ions from both components are ejected from the same fission track. Event-by-event analysis will show that when ions from one of the components are desorbed it is highly likely that ions from the other component will be desorbed from the same track because both components are in close proximity at the nanometre level. If the components exist in separate domains separated by more than 10 nm within the matrix, fission tracks formed in one domain only desorb ions characteristic of that domain. Although the total spectrum is a composite of ions from both domains, the event-by-event analysis makes it possible to determine what fraction of the two matrices reside within the 10 nm dimensions of the fission track.

Concluding Remarks

The ^{252}Cf -PD method has been largely supplanted by MALDI and ESI MS for the analysis of complex biological molecules because these methods are more efficient and widely applicable. The method has stimulated considerable interest in the field of particle-induced desorption and understanding of the mechanisms of the desorption/ionization process. Scanning tunnelling microscopy has been used to characterize the craters produced by fission fragments and high-energy heavy ions from particle accelerators have been used to study the influence of charge, mass and energy on the desorption/ionization process. High-energy cluster ions, including C_{60} fullerene ions, are being used to study the

chemistry and physics of particle-induced energy deposition and transfer and ion emission from solids.

Introduction

Although ³¹P NMR spectra were reported as early as 1951, it was the availability of commercial multinuclear NMR spectrometers in about 1955 that led to the application of ³¹P NMR as an important analytical tool for structure elucidation. Early spectrometers generally required neat samples in large nonrotating tubes (8–12 mm OD). By the mid-1960s NMR became more sensitive and the availability of higher field electromagnets and signal averaging spurred rapid growth in the number of reported ³¹P spectra and the publication of the first monograph devoted to this field.

With the introduction of Fourier-transform (FT) and high-field superconducting-magnet NMR spectrometers in about 1970, ³¹P NMR spectroscopy expanded beyond the study of small organic, organometallic and inorganic compounds to biological phosphorus-containing compounds as well. The latest multinuclear FT NMR spectrometers have reduced if not eliminated the serious limitation to the widespread utilization of phosphorus NMR, which is the low sensitivity of the phosphorus nucleus (6.6% at constant field compared to ¹H NMR; magnetogyric ratio γ , $10.839 \times 10^7 \text{ rad T}^{-1} \text{ s}^{-1}$; NMR

frequency at 4.7 T, 80.96 MHz). Today, routinely, millimolar (or lower) concentrations of phosphorus nuclei in as little as 0.3 mL of solution are conveniently monitored. The ³¹P nucleus has other convenient NMR properties making it suitable for FT NMR: spin $\frac{1}{2}$ (which avoids problems associated with quadrupolar nuclei), 100% natural abundance, moderate relaxation times (providing relatively rapid signal averaging and sharp lines), and a wide range of chemical shifts (> 2000 ppm).

In this article the interpretation of various ³¹P NMR spectroscopic parameters, particularly chemical shifts and coupling constants, will be described. A major emphasis will be placed on developments in ³¹P NMR methods which have considerably expanded the utility of this important spectroscopic probe in organic and biological structure determination.

Practical Considerations

Today's commercial NMR spectrometers cover the ³¹P frequency range from 24 to 323 MHz (on a 800 MHz ¹H NMR spectrometer). Generally, for small, phosphorus-containing compounds, high signal-to-noise and resolution requirements dictate use of as high a magnetic field strength as possible since both sensitivity and chemical-shift dispersion increase at higher operating frequency (and field). However, consideration must be given to field-dependent relaxation mechanisms such as chemical shift anisotropy which can lead to substantial line broadening of the ³¹P NMR signal at high fields. Indeed, especially for larger biomolecules, sensitivity is often poorer at very high fields because of considerably increased line widths. The latest probe designs provide a remarkable improvement in signal-to-noise. Indirect detection 2D NMR experiments have further improved sensitivity.

Typical acquisition times for the 1D ³¹P free induction decay (FID) following a 90° radiofrequency pulse are 1–8 s depending on the required resolution (dictated by the line width of the signal, $1/\pi T_2^*$, where T_2^* is the time constant for the FID). Waiting longer than $2T_2^*$ will generally not improve the signal-to-noise ratio (S/N). Additional consideration for optimization of the S/N must be given to the time it takes for the ³¹P spins to return to thermal equilibrium after a 90° radiofrequency pulse, which is roughly 3 times the spin–lattice relaxation time (T_1). To obtain 99.3% relaxation, a delay of 5 times T_1 is necessary. If

$T_1 \approx T_2^*$, as would be true for small phosphorus-containing molecules where magnetic field inhomogeneity and paramagnetic impurities do not lead to any additional line broadening, then a waiting period between pulses of $3T_2^*$ provides a good compromise between adequate resolution and signal sensitivity. If $T_1 > T_2^*$, as is often the case in larger biomolecular systems, then waiting only $3T_2^*$ does not allow the magnetization to return to equilibrium and an additional delay must generally be introduced so that the total time between pulses is $\sim 3T_1$. This wait can be substantially shortened if the Ernst relationship is used to set the pulse flip angles to $< 90^\circ$. At low field, 60–70° pulses, 4 to 8 k data points and 2.0–5.2 s recycle times are generally used. The spectra are generally broadband ¹H decoupled.

The ³¹P spectra are generally referenced to an external sample of 85% H₃PO₄ or trimethylphosphate which is ~ 3.46 ppm downfield of 85% H₃PO₄. Note that throughout this review the IUPAC convention is followed so that *positive values are to high frequency* (low field). One should cautiously interpret reported ³¹P chemical shifts because the early literature (pre-1970s) and even many later papers use the opposite sign convention.

Quantification of Peak Heights

Historically, the intensity of a resonance has been measured in several ways: (1) peak heights and areas obtained from the standard software supplied by the spectrometer manufacturer, (2) peak heights measured by hand, (3) peaks cut and weighed from the plotted spectrum and (4) peaks fitted to a Lorentzian line shape. For flat baselines, intensity measurements are generally straightforward. However, in the event of curved baselines the measurements are somewhat uncertain and careful baseline correction is necessary.

It is often necessary that experiments be carried out without allowing time for full recovery of longitudinal magnetization between transients because of the limited availability of spectrometer time or of the limited lifetime of the sample. Because of variations in T_1 between different phosphates and variation in the heteronuclear NOE to nearby protons, care should be made in interpretation of peak area and intensities. Addition of a recycle delay of at least $5 \times T_1$ between pulses and gated decoupling only during the acquisition time to eliminate the ¹H–³¹P NOE largely eliminates quantification problems.

³¹P Chemical Shifts

Introduction and Basic Principles

The interaction of the electron cloud surrounding the phosphorus nucleus with an external applied magnetic field B_0 gives rise to a local magnetic field. This induced field shields the nucleus, with the shielding proportional to

the field B_0 so that the effective field, B_{eff} , felt by the nucleus is given by

$$B_{\text{eff}} = B_0(1 - \sigma) \quad [1]$$

where σ is the shielding constant. Because the charge distribution in a phosphorus molecule will generally be far from spherically symmetrical, the ³¹P chemical shift (or shielding constant) varies as a function of the orientation of the molecule relative to the external magnetic field. This gives rise to a chemical-shift anisotropy that can be defined by three principal components, σ_{11} , σ_{22} and σ_{33} , of the shielding tensor. For molecules that are axially symmetrical, with σ_{11} along the principal axis of symmetry, $\sigma_{11} = \sigma_{\parallel}$ (parallel component), and $\sigma_{22} = \sigma_{33} = \sigma_{\perp}$ (perpendicular component). These anisotropic chemical shifts are observed in solid samples and liquid crystals, whereas for small molecules in solution, rapid tumbling averages the shift. The average, isotropic chemical shielding σ_{iso} (which would be comparable to the solution chemical shift) is given by the trace of the shielding tensor or

$$\sigma_{\text{iso}} = \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33}) \quad [2]$$

and the anisotropy $\Delta\sigma$ is given by

$$\Delta\sigma = \sigma_{11} - \frac{1}{2}(\sigma_{22} + \sigma_{33}) \quad [3]$$

or, for axial symmetry,

$$\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp} \quad [4]$$

Theoretical ³¹P Chemical Shift Calculations and Empirical Observations

Three factors appear to dominate ³¹P chemical shift differences $\Delta\delta$, as shown by

$$\Delta\delta = -C\Delta\chi_X + k\Delta n_{\pi} + A\Delta\theta \quad [5]$$

where $\Delta\chi_X$ is the difference in electronegativity in the P–X bond, Δn_{π} is the change in the π -electron overlap, $\Delta\theta$ is the change in the σ -bond angle, and C , k , and A are constants.

As suggested by eqn [5], electronegativity effects, bond angle changes, and π -electron overlap differences can all potentially contribute to ³¹P shifts in a number of classes of phosphorus compounds. While these semi-empirical isotropic chemical-shift calculations are quite useful in providing a chemical and physical understanding for the factors affecting ³¹P chemical shifts, they represent severe theoretical approximations. More exact *ab initio* chemical-shift calculations of the shielding tensor are very difficult although a number of calculations have been reported on phosphorus compounds. Whereas the semi-empirical theoretical calculations have largely supported the importance of electronegativity, bond

angle, and π -electron overlap on ³¹P chemical shifts, the equations relating ³¹P shift changes to structural and substituent changes unfortunately are not generally applicable. Also, because ³¹P shifts are influenced by at least these three factors, empirical and semiempirical correlations can only be applied to classes of compounds that are similar in structure. It should also be emphasized again that structural perturbations will affect ³¹P chemical shift *tensors*. Often variations in one of the tensor components will be compensated for by an equally large variation in another tensor component with only a small net effect on the isotropic chemical shift. Interpretation of variations of isotropic ³¹P chemical shifts should therefore be approached with great caution.

Within these limitations, a number of semiempirical and empirical observations and correlations, however, have been established and have proved useful in predicting ³¹P chemical-shift trends. Indeed, unfortunately, no single factor can readily rationalize the observed range of ³¹P chemical shifts (Figure 1).

Bond Angle Effects

Changes in the σ -bond angles appear to make a contribution ($|A|$, eqn [5]) to the ³¹P chemical shifts of phosphoryl compounds, although electronegativity effects apparently predominate. Empirical correlations between ³¹P chemical shifts and X–P–X bond angles can be found, although success here depends on the fact that these correlations deal with only a limited structural variation: in the case of phosphate esters, it is the number and chemical type of R groups attached to a tetrahedron

of oxygen atoms surrounding the phosphorus nucleus. For a wide variety of different alkyl phosphates (mono-, di-, and triesters, cyclic and acyclic neutral, monoanionic, and dianionic esters), at bond angles $< 108^\circ$ a decrease in the smallest O–P–O bond angle in the molecule generally results in a deshielding (downfield shift) of the phosphorus nucleus.

Torsional Angle Effects on ³¹P Chemical Shifts

Semi-empirical molecular orbital calculations and *ab initio* gauge-invariant-type molecular orbital, chemical-shift calculations suggested that ³¹P chemical shifts are also dependent on P–O ester torsional angles and this has been shown to be of great value in analysis of DNA structure (see below). The two nucleic acid P–O ester torsional angles, ζ (5'-O–P) and α (3'-O–P), are defined by the (5'-O–P–O-3') backbone dihedral angles. These chemical-shift calculations and later empirical observations indicated that a phosphate diester in a *B_I* conformation (both ester bonds *gauche*(–) or -60°) should have a ³¹P chemical shift 1.6 ppm upfield from a phosphate diester in the *B_{II}* conformations (α = *gauche*(–); ζ = *trans* or 180°).

³¹P Signal Assignments

If the proton spectra of the molecule has been previously assigned, then 2D ³¹P–¹H heteronuclear correlation NMR spectroscopy can generally provide the most convenient method for assigning ³¹P chemical shifts in

Figure 2 Pure absorption phase ^{31}P - ^1H heteronuclear correlation spectrum of tetradecamer duplex $\text{d}(\text{TGTGAGCGCTCACA})_2$ at 200 MHz (^1H). ^{31}P chemical shifts are reported relative to trimethyl phosphate which is 3.456 ppm downfield from 85% phosphoric acid. Reproduced with permission.

complex spectra. Whilst application of these experiments to DNA is clear, the 2D methods will of course equally apply to organophosphorus compounds as well.

Conventional 2D ^{31}P - ^1H heteronuclear shift correlation (HETCOR) NMR spectroscopy, the 2D long-range COLOC (correlation spectroscopy via long range coupling) experiment and indirect detection (^1H detection) HETCOR experiments can be used to assign multiple ^{31}P signals in complex spectra such as those of oligonucleotide duplexes. Additional 2D heteronuclear J cross-polarization TOCSY (TOCSY = total correlation spectroscopy), 2D heteronuclear TOCSY-NOESY (NOESY = nuclear Overhauser effect spectroscopy), and even a 3D heteronuclear TOCSY-NOESY experiment can be used if additional spectral dispersion, by adding a third frequency dimension, is desirable. This may prove to be extremely valuable for ribo-oligonucleotides where very little ^1H spectral dispersion in the sugar proton chemical shifts is unfortunately observed.

Generally these 2D experiments correlate ^{31}P signals with coupled ^1H NMR signals. Assuming the ^1H NMR spectra have been assigned, these methods allow for direct assignment of the ^{31}P signals. The HETCOR measurements, however, suffer from poor sensitivity as well as poor resolution in both the ^1H and ^{31}P dimensions, especially for larger biomolecular structures. The poor sensitivity is largely due to the fact that the ^1H - ^{31}P scalar coupling constants are generally about the same size or smaller (except for organophosphorus molecules

with directly bonded hydrogens) than the ^1H - ^1H coupling constants. Sensitivity is substantially improved by using a heteronuclear version of the 'constant time' coherence transfer technique, referred to as COLOC and originally proposed for ^{13}C - ^1H correlations.

An example of a 2D HETCOR spectrum of the self-complementary 14-base-pair oligonucleotide duplex, $\text{d}(\text{TGTGAGCGCTCACA})_2$, is shown in **Figure 2**. The cross-peaks represent scalar couplings between ^{31}P nuclei of the backbone and the H3' and H4' deoxyribose protons. Assuming that the chemical shifts of these protons have been assigned (by ^1H - ^1H NOESY and COSY spectra) the ^{31}P signals may be readily assigned (COSY = homonuclear chemical shift correlation spectroscopy).

Coupling Constants

Directly Bonded Phosphorus Coupling Constants $^1J_{\text{PX}}$

One bond P-X coupling constants (J_{PX}) have generally been rationalized in terms of a dominant Fermi-contact term

$$J_{\text{PX}} = \frac{Aa_{\text{P}}^2a_{\text{X}}^2}{1 + S_{\text{PX}}^2} + B \quad [6]$$

where A and B are constants, a_{P}^2 and a_{X}^2 are percentages character on phosphorus and atom X, respectively, and S_{PX} is the overlap integral for the P-X bond. Because the

Fermi-contact spin-spin coupling mechanism involves the electron density at the nucleus (hence the s-orbital electron density), an increase in the s character of the P–X bond is generally associated with an increase in the coupling constant. The percentages character is determined by the hybridization of atoms P and X, and as expected sp³-hybridized atoms often have ¹J_{PX} larger than p³ hybridized atoms. Thus ¹J_{PH} for phosphonium cations of structure PH_nR_{4-n}⁺ with sp³ hybridization are ~500 Hz, whereas ¹J_{PH} for phosphines PH_nR_{3-n} with phosphorus hybridization of approximately p³ are smaller, ~200 Hz. Furthermore, as the electronegativity of atom X increases, the percentages character of the P–X bond increases, and the coupling constant becomes more positive. In many cases, however, these simple concepts fail to rationalize experimental one-bond P–X coupling constants (Table 1) because other spin-spin coupling mechanisms can also contribute significantly to the coupling constant. For tetravalent phosphorus, a very good correlation is found between ¹J_{PC} and the phosphorus 3s–carbon 2s bond orders, the percentages s in the P–C bonding orbital in going from alkyl to alkenyl to alkynyl (sp³ → sp² → sp), and ¹J_{PC}. Calculations and empirical observations on trivalent phosphorus compounds are *not* successful however, and suggest that the Fermi-contact contribution only dominates tetravalent phosphorus compounds.

One-bond P–H coupling constants appear always to be positive and vary from about +120 to +1180 Hz. Other heteroatom one-bond P–X coupling constants vary over a similar wide range and can be either positive or negative. The expected range of values is given in Table 1.

Two Bond Coupling Constants: ²J_{PX}

Two-bond ²J_{PX} coupling constants may be either positive or negative and are generally smaller than one-bond coupling constants (Table 2). The ²J_{PCH} and ²J_{PCF} constants are stereospecific and a Karplus-like dihedral dependence to the two-bond coupling constant (H or F)–C–P–X (X = lone pair or heteroatom) has been found. Thus in the *cis*- and *trans*-phosphorinanes, the ²J_{PC} constants are 0.0 and 5.1 Hz in the *cis*- and *trans*-isomers, respectively.

Three-Bond Coupling Constants, ³J_{PX}

Three-bond coupling constant, ³J_{PX}, through intervening C, N, O, or other heteroatoms are generally < 20 Hz (Table 3). The dihedral-angle dependence of vicinal ³J_{POCH} coupling ³J_{PCCH} and ³J_{PCCC} has been demonstrated. The curves may be fitted to the general Karplus equation

$$J(\phi) = A \cos^2 \phi + B \cos \phi + C \quad [7]$$

where ϕ is the dihedral angle and *A*, *B* and *C* are constants for the particular molecular framework. Caution is

determine the conformation about the ribose–phosphate backbone of nucleic acids in solution. Torsional angles about both the C3'–O3' and C5'–O5' bonds in 3',5'-phosphodiester linkages have been determined from the coupled ¹H and ³¹P NMR spectra.

^aFor structural classes, only the absolute value for *J* is given.

Within the limitations just described for the general application of the Karplus relationship, the best Karplus relationship for the nucleotide H3'–P coupling constants appears to be

$$J = 15.3 \cos^2(\theta) - 6.1 \cos(\theta) + 1.6$$

From the H3'–C3'–O–P torsional angle θ , the C4'–C3'–O–P torsional angle ε ($= -\theta - 120^\circ$) may be calculated.

The *J*_{H3'–P} coupling constants in larger oligonucleotides cannot generally be determined from the coupled 1D ³¹P or ¹H spectra because of spectral overlap. 2D *J*-resolved long-range correlation pulse sequences can be used to overcome this limitation. The Bax–

Freeman selective 2D J experiment with a DANTE (delays alternating with nutations for tailored excitation) sequence for a selective 180° pulse on the coupled protons can be readily implemented on most spectrometers. This is particularly useful for measuring phosphorus–H3' coupling constants in duplex fragments, which can vary from ~ 1.5 to 8 Hz in duplexes as large as tetradecamers. There is a strong correlation ($R = -0.92$) between torsional angles $C4'-C3'-O3'-P$ (ε) and $C3'-O3'-P-O5'$ (ζ) in the crystal structures of various duplexes. Thus both torsional angles ε and ζ can often be calculated from the measured P–H3' coupling constant.

Coupling constants of both 5' protons are analysed in order to determine conformations about the $C5'-O$ bond. Unfortunately, these β torsional angles have in practice been generally unobtainable even in moderate-length duplexes. Selective 2D J -resolved spectra generally fail for H4', H5' or H5'' coupling to ^{31}P because the spectral dispersion between these protons is so limited. However, with either ^{13}C labelling or even natural abundance ^{13}C methods, it is possible to measure not only the ^1H – ^{31}P but also the ^{13}C – ^{31}P coupling constants. Analysis of the 2D multiplet pattern, especially the 'E. COSY' pattern of the ^1H – ^{13}C HSQC spectrum, has allowed extraction of many carbon ($C3'$, $C4'$, $C5'$) and proton ($H3'$, $H4'$, $H5'$, $H5''$) coupling constants to phosphorus. The larger line widths of longer duplexes limit measurement of the small coupling constants.

As shown in **Figure 3**, the Karplus relationship provides for four different torsional angle solutions for each value of the same coupling constant. Although all four values are shown in **Figure 3**, the limb which includes ε values between 360° and -270° is sterically inaccessible in nucleic acids. As shown in **Figure 3**, nearly all of the phosphates for normal Watson–Crick duplexes fall along only a single limb of the Karplus curve. Thus, for 'normal' B-DNA geometry, there is an excellent correlation between the phosphate resonances and the observed

torsional angle, while phosphates that are greatly distorted in their geometry must be more carefully analysed.

It is clear from **Figure 3** that ^{31}P chemical shifts and coupling constants provide probes of the conformation of the phosphate ester backbone in nucleic acids and nucleic acid complexes. It is important to remember that ^{31}P chemical shifts are dependent on factors other than torsional angles alone. As noted above, ^{31}P chemical shifts are very sensitive to bond angle distortions as well. It is quite reasonable to assume that backbone structural distortions as observed in unusual nucleic acid structures also introduce some bond angle distortion as well. Widening of the ester O–P–O bond angle indeed is expected to produce an upfield shift, while narrowing of this bond angle causes a downfield shift, and it is possible that this bond angle effect could account for the anomalous shifts. Indeed, very large ^{31}P chemical shift variations (~ 3 –7 ppm) are observed in transfer RNA and hammerhead RNA phosphates, and are probably due to bond angle distortions in these tightly folded structures.

Generally the main-chain torsional angles of the individual phosphodiester groups along the oligonucleotide double helix are responsible for sequence-specific variations in the ^{31}P chemical shifts. In duplex B-DNA, the gauche(–), gauche(–) (g^- , g^- ; ζ , α) (or B_I) conformation about the P–O ester bonds in the sugar phosphate backbone is energetically favoured, and this conformation is associated with a more shielded ^{31}P resonance. In both duplex and single stranded DNA the trans, gauche(–) (t , g^- ; ζ , α) (or B_{II}) conformation is also significantly populated.

The ^{31}P chemical shift difference between the B_I and B_{II} phosphate ester conformational stages is estimated to be 1.5–1.6 ppm. As the result of this sensitivity to the backbone conformational state, ^{31}P chemical shifts of duplex oligonucleotides have been shown to be dependent upon both the sequence and the position of the phosphate residue.

Figure 3 Plot of ^{31}P chemical shifts for duplex oligonucleotide sequences ($\circ$) and an actinomycin D bound $d(\text{CGCG})_2$ tetramer complex ($\square$) with measured $J_{\text{H}3'-\text{P}}$ coupling constants ($\bullet$, phosphates in a tandem GA mismatch decamer duplex which shows unusual, slowly exchanging signals). Also shown are the theoretical ε and ζ torsion angles (solid curve) as a function of the coupling constant derived from the Karplus relationship (ε) and the relationship $\zeta = -317 - 1.23\varepsilon$. ^{31}P chemical shifts are reported relative to trimethyl phosphate. Reproduced with permission.

The possible basis for the correlation between local helical structural variations and ³¹P chemical shifts can be analysed in terms of deoxyribose phosphate backbone changes involved in local helical sequence-specific structural variations. As the helix winds or unwinds in response to local helical distortions, the length of the deoxyribose phosphate backbone must change to reflect the stretching and contracting of the deoxyribose phosphate backbone between the two stacked base pairs. To a significant extent, these changes in the overall length of the deoxyribose phosphate backbone 'tether' are reflected in changes in the P–O ester (as well as other) torsional angles. These sequence-specific variations in the P–O (and C–O) torsional angles may explain the sequence-specific variations in the ³¹P chemical shifts.

³¹P NMR of Protein Complexes

³¹P NMR spectroscopy has proven to be very useful in the study of various protein complexes. **Table 4** provides an indication of the range of ³¹P chemical shifts and the titration behaviour of various phosphoprotein model compounds. Two examples of such studies are described below.

Table 4 Chemical shifts and pH titration data for representative model compounds

Compound	Chemical shift (ppm) ^a	Titrateable ^b	pK _a
Phosphomonoesters			
Phosphoserine	4.6	+	5.8
Phosphothreonine	4.0	+	5.9
Pyridoxal phosphate	3.7	+	6.2
Pyridoxamine phosphate	3.7	+	5.7
Flavin mononucleotide	4.7	+	~6.0
Phosphodiester

Diphosphodiester			
Flavin adenine dinucleotide	-10.8 to -11.3	–	
Phosphotriesters			
Dialkyl phosphoserine	0 to -3.0	–	
Phosphoramidates			
N ³ -Phosphohistidine	-4.5	–	
N ¹ -Phosphohistidine	-5.5	–	
Phosphoarginine	-3.0	+	4.3
Phosphocreatine	-2.5	+	4.2
Acyl phosphates			
Acetyl phosphate	-1.5	+	4.8
Carbamyl phosphate	-1.1	+	4.9

^aAll chemical shifts are reported with respect to an external 85% H₃PO₄ standard; upfield shifts are given a negative sign.

^bTitrateability: + indicates that changes are observed in the chemical shift on changes in pH: for phosphomonoesters this change is 4 ppm; for phosphoramidates 2.5 ppm; for acyl phosphates 5.1 ppm; – indicates no change observed.

Ribonuclease A

Secondary ionization of a phosphate monoester produces approximately a 4 ppm down field shift of the ³¹P signal. Thus the pH dependence of the ³¹P signal of various phosphate monoesters bound to proteins can provide information on the ionization state of the bound phosphate ester. For example, pyrimidine nucleotides, both free in solution and when bound to bovine pancreatic ribonuclease A (RNase A), demonstrate this point. The ³¹P chemical shift of free solution cytidine 3'-monophosphate (3'-CMP) follows a simple titration curve, and the ionization constant derived from the ³¹P shift variation agrees with potentiometric titration values. The ³¹P chemical shift titration curve for the 3'-CMP · RNase A complex, however, cannot be analysed in terms of a single ionization process. Two inflections observed in this titration indicated two ionizations with pK₁ = 4.7 and pK₂ = 6.7.

These results suggest that the nucleotide binds at around neutral pH in the dianionic ionization state. Thus the 3'-CMP · RNase A complex ³¹P resonance is shifted upfield less than 0.3 ppm from the free 3'-CMP between pH 6.5 and 7.5, whereas monoprotection of the free dianion results in a 4 ppm upfield shift. Furthermore, the addition of the first proton to the nucleotide complex (pK₂ = 6.0–6.7) must occur mainly on some site other than the dianionic phosphate because the ³¹P signal is shifted upfield by only 1–2 ppm. The addition of a second proton (pK₁ = 4.0–5.7) to the complex shifts the ³¹P signal further upfield so that at the lowest pH values, the phosphate finally appears to be in the monoanionic ionization state.

On the basis of X-ray and ¹H NMR studies, it is known that the nucleotides are located in a highly basic active site with protonated groups histidine-119, histidine-12 and, probably, lysine-41, quite close to the phosphate. This suggests that pK₁ is associated with ionization of a protonated histidine residue which hydrogen bonds to the phosphate. This highly positive active site, which is capable of perturbing the pK of the phosphate from 6 to 4.7, must have one or more hydrogen bonds to the phosphate over the entire pH region. Yet at the pH extrema, little if any perturbation of the ³¹P chemical shift is found. Apparently, the ³¹P chemical shift of the phosphate esters is largely affected by the protonation state and not by the highly positive local environment of the enzyme.

Two-Dimensional Exchange ³¹P NMR of Phosphoglucosyltransferase

Phosphoglucosyltransferase (PGM) catalyses the interconversion of glucose 1-phosphate and glucose 6-phosphate. The enzyme has 561 residues on a single polypeptide chain with molecular weight 61 600 Da. Catalysis

proceeds via a glucose 1,6-bisphosphate intermediate where the formation and breakdown of this intermediate results from two phosphate transfer steps involving a single enzymic phosphorylation site, Ser-116. A metal ion is required for activity and the most efficient metal ion is the physiological activator, Mg²⁺. The phosphate transfer steps are shown below.

E_P and E_D are the phospho and dephospho forms of the enzyme, respectively, Glc1P is glucose 1-phosphate and Glc6P is glucose 6-phosphate.

Metal-free PGM and complexes with a variety of metal ions, substrates and substrate analogues have been studied by ³¹P NMR. Under conditions where the enzyme is inactive, each of the three enzyme-bound intermediates in the above scheme can be studied.

Exchange processes can be detected by 2D ³¹P NMR in addition to the conventional 1D methods. The 2D exchange experiment (NOESY) described by Ernst and co-workers involves three 90° pulses. Nuclei are frequency labelled by a variable delay time (*t*₁) separating the first and second pulses. The mixing time is between the second and third pulses, and the detection of transverse magnetization as a function of time (*t*₂) follows the third pulse. During the mixing time, nuclei labelled in *t*₁ with a frequency corresponding to one site are converted by the exchange processes to a second site and evolve in *t*₂ with the frequency of the second site, giving rise to cross-peaks in the 2D spectrum. A 2D ³¹P exchange spectrum of PGM shows cross-peaks indicating exchange between bound Glc6P and free Glc6P and between the two bound phosphorus sites, indicating transfer through free E_P involving a full catalytic cycle (see eqn [8]).

Medical Applications of ³¹P NMR

In vivo ³¹P NMR spectroscopy and ³¹P magnetic resonance imaging are also important applications of this nucleus. ³¹P signals from inorganic phosphate, adenosine triphosphate, adenosine diphosphate, creatine phosphate and sugar phosphates can be observed in whole-cell preparations, intact tissues, and whole bodies and can provide information on the viability of the cells and tumour localization. Low sensitivity continues to be a problem in widespread application of these techniques.

Additional details can be found in several of the entries in the Further Reading section.

Conclusions

³¹P NMR has become an indispensable tool in studying the chemistry and reactivity of phosphorus compounds, as well as in studying numerous biochemical and biomedical problems. Newer NMR instrumentation has enormously enhanced the sensitivity of the experiment and allowed 2D NMR studies to provide new means of signal assignment and analysis. Through 2D and 3D heteronuclear NMR experiments it is now possible to unambiguously assign the ³¹P signals of duplex oligonucleotides and other phosphate esters. Both empirical and theoretical correlations between measured coupling constants, ³¹P chemical shifts, and structural parameters have provided an important probe of the conformation and dynamics of nucleic acids, protein complexes, and small organophosphorus compounds.

The two techniques of Raman and infrared (IR) spectroscopy have some similarities, yet are quite different in a number of ways. They provide complementary vibrational information. The reader is referred to the articles on the fundamentals of these techniques for details. Raman and IR will here be collectively referred to as VS (vibrational spectroscopy), except where details of a particular technique warrant discussion. It should also be noted that most of the techniques mentioned can also be used with near-IR radiation, but specific examples will not be cited.

Among the large number of applications of VS, applications to polymeric systems are especially interesting because of the wide variety of chemical structures and physical ordering that is present in polymer systems. The article is arranged as follows. First, the application of VS to the determination of chemical properties of polymeric systems will be illustrated. In particular, the use of VS as an identification tool for complex polymeric systems and the application of VS to the various chemical reaction processes will be detailed. Then the application of VS to the determination of polymer structure on a wide range of length scales will be explained, with particular emphasis on the determination of stereoregularity, chain conformation and crystallinity. The remainder of the article will focus on the study of dynamic properties of polymers such as diffusion and rheological properties and topics such as millisecond time-resolved and microimaging applications.

Spectroscopic Considerations Unique to Polymers

In contrast to small-molecule compounds, in polymer molecules the atoms are all linked together to form long chains. The presence of such long chains causes additional vibrational modes to be present that do not exist in small-molecule analogues. These arise owing to the vibrations of the chain as a whole. This topic is best treated using classical physics and normal coordinate analysis, which is beyond the scope of this article. A more indepth discussion of these topics can be found in the books by Koenig listed in Further Reading. In addition, the long chains can possess ordering along the chain as well as between neighbouring chains. This quality is also unique to polymers and is responsible for many of the physical properties that make polymers the material of choice for a wide variety of applications.

Several properties of polymers complicate their analysis via VS. First, a problem unique to transmission IR spectroscopy is that polymers are very strong absorbers of IR radiation. Therefore, in order to be within the linear region of Beer's law, an extremely thin polymer film must be used in transmission. A good rule of thumb is to keep the thickness below 5 μm . While the production of such thin films is possible in the laboratory, it must be remembered that most commonly encountered polymer systems are much thicker than this. As a result, the most commonly used industrial IR techniques are reflectance techniques such as attenuated total reflectance (ATR) or reflection-absorption spectroscopy (RAS), which have much smaller effective optical path lengths, typically on the order 1 μm or below.

A problem unique to Raman spectroscopy is the fact that most polymers fluoresce strongly when exposed to laser radiation. This problem can be reduced by using Fourier transform and resonance Raman techniques. Because of this and other difficulties associated with Raman spectroscopy, the quality of Raman spectra of polymers is typically less than that of IR spectra. Therefore, it is not surprising that a quick search of the literature reveals many more quantitative studies of polymers using IR than using Raman.

Using a combination of IR and Raman spectroscopies can yield valuable information. IR spectroscopy is sensitive to any chemical groups that possess a significant

dipole moment, such as C–H, and C=O, which are commonly found in polymer side groups. Raman spectroscopy is more sensitive to highly polarizable groups such as C–C and C=C, which are commonly found in the polymer chain backbone. Thus, when used together, IR and Raman spectroscopy can be used to gain more information than is available from either of the individual techniques.

Complete Structure Determination

VS can be used in the complete chemical and physical structure determination of polymers. Four size scales of structure and orientation found in polymers are covered. The most basic is the chemical identity of the chains, including chemical groups present, monomer sequences and stereoregularity. This is followed by studies of the local conformation of individual chains and interactions between chains, and finally orientation induced by the application of macroscopic forces.

Chemical Identity of Polymer Chains

The techniques used for identification of the basic chemical structure of polymer chains are similar to those used for small molecules. The difference is that there is not a single chemical structure present; rather there is a distribution of chemical structures. The semirandom statistics involved in the polymerization reaction produce a distribution of molecular masses. Therefore, an average molecular mass is reported. Although chromatography and light scattering are most commonly used for molecular mass determination, IR can provide complementary chemical structure information. A number-average relative molecular mass, M_n , can be obtained by determining the number of end groups present for a given amount of polymer by

$$M_n = \frac{2}{E_{\text{end}}}$$

where E_{end} is the number of mass equivalent weights of end groups per gram of polymer, as determined from a simple Beer's law treatment. This method works if the structure of the end groups and the nature of the polymerization process are known.

Another unique property of polymerization and copolymerization reactions is the presence of a distribution of chemical connectivities in the final polymer, which come about from the orientation of monomer addition. This is commonly referred to as regiochemistry or regioisomerism. In a typical monosubstituted vinyl polymerization, the monomer has two options of addition to the growing chain, commonly referred to as head or tail addition, depending on whether the propagating

chain attacks the monomeric carbon with the pendant group or the unsubstituted carbon, respectively. The ratio of head-to-head, head-to-tail, etc. groups present in the final polymer can be determined by comparing the ratios of spectral bands associated with these linkages. In a similar manner, copolymer systems can be analysed to determine the statistics of the polymerization process. NMR is the most commonly used technique for this type of analysis, but not all polymers can be analysed using this method. VS can be used in these cases and also to verify the NMR results.

Perhaps the most common application of VS in the determination of chemical makeup in polymeric systems is the identification of components in complex polymer mixtures. Polymeric products are rarely composed of a single component. There are always additives present that aid in processing, appearance, adhesion, chemical stability or other properties important to the function of the final product. In an industrial setting, it is important to be able to determine both the identity and quantity of polymers and additives in a specific formulation for quality control purposes. This can be a fairly routine operation if tools such as spectral libraries are utilized. In this method, a computer search algorithm compares a spectrum with a catalogue of standard spectra to determine the identity of the compound or compounds present. Advanced statistical techniques, such as partial least squares (PLS) and principal-component analysis (PCA), are also often used to identify known and unknown components in polymeric systems. The details of these methods are described elsewhere in the Encyclopedia.

In certain polymerization processes, the final polymer may contain side branches. The most notable example of this is polyethylene, which commonly contains short branches that result from chain transfer reactions during the polymerization process. For each type of branch, up to six carbons in length, the methyl rocking band around 900 cm^{-1} has a unique frequency. By comparing the intensities of these branch peaks to peaks associated with the main chain, the relative amount of each type of branch can be determined.

Owing to the length of typical polymer chains, the arrangements of side groups along the chain becomes important in the determination of the chemical properties of the polymer. The polymerization process permanently locks in this arrangement of side groups. The persistence of a specific pattern along the entire chain is known as stereoregularity. Stereoregular effects appear in vibrational spectra as spectral peak splitting or other changes in band shape. An example is shown in **Figure 1**, which shows the IR spectra from the three pure stereoisomers of polystyrene. As can be seen, the bands around 1070 , 550 and 900 cm^{-1} are quite different for each stereoisomer, revealing that the local molecular environments are different in each case.

Figure 1 Infrared spectra of the pure stereoisomers of polystyrene.

Orientation of a Single Polymer Chain

The next highest level of order in polymer chains is the presence of rotational isomers, which result from stable configurations of the polymer chain. The presence of *cis* and *trans* configurations and the relative ratios of each can be determined using VS because each of these structures possesses a unique spectral band. Owing to the complementary nature of IR and Raman spectroscopy, a wealth of information about the chain conformation can be determined. Raman is particularly useful in this application owing to its enhanced sensitivity to the local environments around carbon-carbon bonds in the chain backbone. Using a simple thermodynamic treatment, this technique can be extended to determine quantitatively the activation energy barrier between the two conformers. The kinetic rate constant, k , can be determined from spectral information using the expression:

$$k = \frac{A_1/a_1}{A_2/a_2}$$

where A_1 and A_2 are the absorbances of the bands associated with each conformer, and a_1 and a_2 are the corresponding extinction coefficients of the bands. By acquiring spectra at a range of different temperatures, the activation energy, ΔG , can be determined from the

well-known relation

$$\Delta G = RT \ln k$$

where R is the gas constant and T is the temperature.

Stable crystalline forms arise from the propagation of a particular sequence of conformations along the entire length of the chain, resulting in a helical arrangement. The most commonly used method for analysing crystalline materials is X-ray diffraction, which can detect long-range crystalline order, like that found in semicrystalline polymers such as poly(vinylidene fluoride) and polyethylene. VS probes the local molecular environment, and therefore has the advantage over X-ray methods that it can detect the short-range order present in the amorphous phase. The presence of helical order shows up in a predictable manner in both IR and Raman spectra.

VS has been applied to polystyrene, which can possess several localized crystalline forms. In this particular case, order results from a planar zigzag arrangement of the chains that pack together to form structures that possess either trigonal or orthorhombic symmetries. As subtle as this ordering may seem, it can be detected effectively using VS. This can be seen in **Figure 2**, which shows that the pure crystalline forms of syndiotactic polystyrene have distinct IR spectra. This particular example illustrates the

Figure 2 Infrared spectra of polystyrene with (curve a) a mixture of crystalline and amorphous forms, (curve b) a mixture of crystalline forms only, (curve c) one 'pure' crystalline form obtained by spectral subtraction, (curve d) another 'pure' crystalline form obtained by spectral subtraction and (curve e) subtraction result of curves b – c – d. Reproduced with permission of John Wiley & Sons Limited from Musto P, Tavone S, Guerra G, and DeRosa C (1997) Evaluation by Fourier transform infrared spectroscopy of the different forms of syndiotactic polystyrene samples. *Journal of Polymer Science B* 35: 1055–1066.

spectral subtraction technique used to determine the spectra of pure crystalline forms of polymers. The spectrum from a completely amorphous sample is subtracted from the spectrum of a partially crystalline sample to yield the 'pure' crystalline spectrum. This is repeated for all crystalline forms. Using these spectra, the crystal forms present in any sample can then be determined. This method of spectral subtraction is commonly used to isolate the spectral contributions of individual components to determine which structures are present.

Interactions Between Chains

To achieve desirable properties, polymers are often blended to form stable mixtures. The formation of successful polymer blends depends on the presence of favourable interactions, such as hydrogen bonding, between chains. These strong interactions show up in the vibrational spectra as the appearance or disappearance of peaks or as peak shifts. The most commonly studied blend systems involve polymers with carbonyl groups, which show different carbonyl bands for hydrogen-bonded and nonbonded groups. In these studies, the degree of compatibility can be determined by monitoring the spectral shifts and relative peak intensities of the bonded and nonbonded forms for a range

of concentrations and temperatures. With the proper mathematical treatment, thermodynamic and kinetic parameters for these processes can be determined. The details are described in depth in the book by Coleman et al. (see Further Reading). This technique has also been used to probe the interactions between polymers that do not contain such obvious interacting groups, such as the classic totally miscible pair polystyrene and poly(phenylene oxide).

Orientation Induced by Processing

The production of polymer products typically involves processes in which the polymer is raised above its glass transition temperature (T_g) and forced into some desired shape. The most common of these methods include injection moulding and blow moulding and depend on the desired geometry of the final product. During this process, the highly flexible polymer chains in different parts of the mould orient according to the local shear and elongational stresses. These stresses cause orientation of both the crystalline and amorphous regions of the polymer and can produce ordered regions with undesirable anisotropic mechanical properties in the final products. This orientation can be measured using a variety of methods involving transmission, ATR or RAS depending on the

sample geometry and transparency. These reflectance methods are especially useful for determining the orientation at or near the surface of the finished product. The three-dimensional orientation of the chains near the surface can be quantified in this manner.

The most commonly used method for quantifying the extent of orientation in polymeric systems is the determination of the dichroic ratio. Two spectra are collected: one with radiation polarized parallel to a reference direction and one perpendicular to this direction. The reference direction is most commonly chosen along the direction of orientation. The ratio of these two spectra, often called the dichroic ratio spectrum, can then be used to characterize the orientation in the system. Dichroic ratios greater than unity indicate orientation along the reference direction, while those less than unity indicate orientation in the orthogonal direction. A value of 1 is indicative of a lack of orientation.

It should also be noted that the presence of orientation in samples can give rise to errors in quantitative studies. The presence of orientation changes the measured absorbance values, which affects the results of quantitative analysis. One way around this is to calculate the equivalent absorbance value with no orientation, the so-called structure factor A :

$$A = \frac{A_x + A_y + A_z}{3}$$

where A_x , A_y and A_z represent the absorbances obtained with x , y and z polarization, respectively. The structure factor is then used in place of absorbance in quantitative studies.

The behaviour of polymers can also be followed using a time-resolved technique known as rheoptical spectroscopy or dynamic IR linear dichroism (DIRLD). In this technique, a strain is applied to a polymer sample, and the spectral changes are monitored over time. This strain is usually either a sinusoid or a step function, these being the easiest to reproduce experimentally. With the inclusion of stress and strain gauges, the spectral changes can be directly related to the mechanical properties. This technique has been used to directly study strain-induced conformational changes. A more advanced application is the study of the mechanical behaviour of polymer blends. When a miscible blend is examined, it can be seen that the spectral bands corresponding to different chains respond in phase, implying that they are molecularly mixed and act as one unit. The spectral responses have different phases for an immiscible blend, which shows that each polymer functions alone.

Chemical Property Determination

Polymerization Reactions

Perhaps the most obvious chemical application is the monitoring of polymerization reactions involved in the

production of polymers. Like most chemical reactions, the polymerization process shows up very well in vibrational spectra as the simultaneous disappearance and appearance of spectral bands. For example, in the polymerization of a typical vinyl monomer, carbon-carbon double bonds are broken and carbon-carbon single bonds are formed. This can be seen clearly in the spectra as the disappearance of the vinyl stretch band around 1500 cm^{-1} and the simultaneous appearance of carbon-carbon single-bond stretching bands and aliphatic carbon-hydrogen stretching bands. This technique can be used to determine both the kinetic order of the polymerization reaction and the kinetic rate constants.

On-line monitoring has also received much recent interest in this area. This application allows spectra to be collected during the polymerization reaction without the necessity of stopping the reaction or performing the experiment under restrictive laboratory conditions. With the advent of low-loss fibreoptics, it is possible to monitor a polymerization reaction in a variety of harsh conditions far away from the spectrometer. This is particularly useful for large production settings commonly found in the polymer industry. An example of the quality of spectra that can be obtained using this method is shown in **Figure 3**, which shows several spectra from different times during a copolymerization reaction between styrene and 2-ethylhexyl acrylate. As can be seen, the quality of the spectra is quite good despite the drastic experimental conditions.

Several types of reactions involving polymers themselves have been studied using VS, including cross-linking, vulcanization and degradation. The same methods are used for these processes as are used to study polymerization reactions.

Time-Dependent Phenomena and Spatially Resolved Studies

VS is perhaps the most frequently used technique for the study of diffusion in polymeric systems because it provides a rapid way to quantitatively describe this phenomenon. The two areas of this type of research include the diffusion of small molecules into polymers and polymer-polymer interdiffusion. The easiest and most commonly used technique for this purpose is ATR. In this experiment, a polymer film is placed in contact with an ATR crystal, and the diffusing species is placed on top of the polymer. As diffusion progresses, the diffusing species moves closer to the ATR crystal and shows up in the spectrum obtained as an increase in the diffusing species specific spectral band. This spectral change can be used to determine the diffusion coefficient of the system with the appropriate diffusion equation. This technique is limited to IR because of the optics and sample geometry required.

Figure 3 *In situ* infrared spectra measured during the progress of a copolymerization reaction using a fibreoptic probe. Reproduced with permission of John Wiley & Sons Limited from Chatzi EG, Kammona O, and Kipanssides (1997) Use of a midrange infrared optical-fiber probe for the on-line monitoring of 2-ethylhexyl acrylate/styrene emulsion copolymerization. *Journal of Applied Polymer Science* 63: 799.

A more modern approach to this problem is to use microscopic techniques, such as an IR microscope or Raman microprobe, which directly monitor the movement of diffusing species. In this technique, the contact method is used, in which a thin film of polymer is placed into edge-on contact with the diffusing species. After diffusion has been allowed to progress for a certain period of time, the diffusion process is stopped by quenching, and spectra are collected along the diffusion direction to yield spatially resolved concentration information. As in the ATR method, these data are fitted to the appropriate diffusion equation to yield a diffusion coefficient. This method is more difficult to apply than ATR because of the difficulty in sample preparation, but it has the advantage of utilizing a simplified diffusion equation.

A recent trend is the incorporation of two-dimensional detectors into IR and Raman microscopes. For IR studies, focal plane array detectors are used, while charge-coupled device (CCD) detectors are used for Raman studies. When combined with the appropriate hardware, these systems are capable of collecting images of high spatial and spectral resolution in a matter of a few minutes. This allows systems that vary in time to be monitored *in situ*, and in real time depending on the rapidity of the process under study. This technique has the advantage of producing spatially resolved, chemically specific spectral images, which aids in the visualization of the process, in addition to providing high-fidelity quantitative information. An example of the quality of data that can be obtained is shown in **Figure 4**, which shows a diffusion profile obtained using an IR microscope equipped with a 64×64 element focal plane array detector. The normalized absorbance values of the diffusant

peak are plotted against diffusion distance and fitted to a Fickian diffusion profile, which is also shown. This data was extracted from an image that was acquired in less than 3 minutes.

The determination of the spatial distribution of chemical species in polymeric systems is perhaps the most basic and most commonly encountered use of microspectroscopy. This technique is frequently used for the identification of defects in finished polymer products and for the identification of phase-separated regions of polymer blends. Polymer laminate films, which typically consist of layers between 2 and $10\text{ }\mu\text{m}$ thick, are also frequently studied using this technique. Raman techniques are typically more useful than IR techniques owing to the higher spatial resolution attainable. This is shown in **Figure 5**, which shows Raman spectra obtained from $10\text{ }\mu\text{m}$ regions of a laminate film. As can be seen, the identity of each layer can be distinguished from the others by the spectral features. Another technique, known as confocal Raman microscopy, allows the acquisition of spectra from thin regions, typically around $1\text{ }\mu\text{m}$, through the depth of the sample. This method has advantages over other methods because it can be used as a nondestructive quality control test to determine the thickness and chemical identity of the individual layers of a thin film.

An additional technique that can obtain spatially resolved spectral information is step-scan photo-acoustic IR spectroscopy. Spectra can be obtained from different depths of a layered sample quickly and with higher spatial resolution (in some cases less than $1\text{ }\mu\text{m}$) than the diffraction-limited optics of IR microscopes are capable of obtaining.

Mechanical Property Determination Using Raman Spectroscopy

An interesting application of Raman spectroscopy is in the determination of the modulus of pure crystalline forms of a polymer. Raman is very sensitive to the longitudinal acoustic vibrational modes of simple polymer chains. Using a combination of normal coordinate analysis and experiment, the modulus of pure crystalline forms of simple straight-chain polymers, such as polyethylene and

poly(oxymethylene), have been determined. Similar techniques have been used to study the pressure-dependent band shifts that occur when a polymer sample is placed under stress. This technique is complementary to mechanical analysis because it gives insight into what is occurring at the molecular level during mechanical deformation.

Introduction: Synthetic Polymers

Synthetic polymers, with repeat unit numbers of a few tens up to millions, are chemically simpler than their biological counterparts (proteins, DNA, polysaccharides). Homopolymers ideally consist of only one and the same repeat unit (monomer), and copolymers have a few, up to maybe three or four, chemically different monomers. Nevertheless, synthetic polymers are characterized by a wide complexity in their structure and dynamics, and this article highlights the possible investigation of a variety of important aspects in this field by nuclear magnetic resonance (NMR). Complexity in synthetic polymers arises for different reasons, which will be summarized in this section.

Generally, one can distinguish different linear and branched chain architectures, as shown in **Figure 1**. The different branch points in such structures are readily distinguishable by NMR, provided their concentration is high enough. However, the most important structural aspects arise more locally within the chains. First, and in contrast to most biological macromolecules, weakly hindered rotation around different bonds is usually possible, giving rise to different conformational states, and these exhibit distinct chemical shifts in many cases. For the *trans* and *gauche* conformations of a saturated alkane chain (=polyethylene) sketched in **Figure 1**, a ^{13}C chemical shift difference of -5.2 ppm arises due to the so-called γ -*gauche* effect, which describes changes in shielding when main- or side-chain atoms, that are separated by three bonds, come closer to each other for a specific conformation. For other substituents or compositions, the effect can be even bigger (-7.2 ppm for $\text{C}_0\cdots\text{O}_\gamma$). Depending on the physical state (solutions of varying viscosity, bulk

Figure 1 Overview of different polymer architectures and relationship of large-scale chain flexibility and local conformational freedom. The γ -*gauche* effect on the ^{13}C chemical shift of C_0 arises from the closer approach of C_0 and C_γ in the *gauche* conformation (3 Å as opposed to 4 Å, see arrow).

melt, or glassy state), the different conformations either interconvert rapidly, leading to the observation of a Boltzmann-weighted average chemical shift, or are fixed on the timescale defined by the inverse frequency separation, leading to the observation of distinct shifts for distinct conformations. In molten polyethylene, the ^{13}C shift differs by ~ 2 ppm from the all-*trans* conformation, the latter being independently measurable on the crystalline phase. If the three conformations were equally populated, an average shift of $2 \times 5.2/3 = 3.5$ ppm would be expected. The lower observed shift indicates that the *trans* conformation is favored. The intermediate situation corresponds to the well-known scenario of chemical shift exchange and coalescence, and is characterized by broad lines. Such a line broadening may either be a valuable source of information on conformational dynamics, or can be avoided by heating or cooling, or using a more or less viscous solvent.

Second, despite their chemical regularity, local configurations may well be different, and in this regard, geometrical and positional isomerism, as well as stereochemistry, plays an important role. Geometrical and positional isomers arise when polymerizable monomers can be attached to each other in different ways, for example head-to-tail versus head-to-head connections. This leads to distinctly different structural motifs and consequently, to meaningful differences in the NMR spectra, readily interpreted by standard rules and procedures. Depending on the specific mode of polymerization, such forms of isomerism are usually easy to control by the specific chemistry, leaving stereoisomerism as a more important structural parameter.

Stereochemical sequence analysis is thus the most frequently studied aspect in solution-state NMR of polymers, as the stereoregularity is in most cases the dominant factor that determines to which extent the polymer is semicrystalline or amorphous, with a large impact on the physical properties of the material. In vinyl polymers, a stereoregular polymer is either isotactic or syndiotactic. These two tacticity patterns differ in the stereochemical diad composition (*meso*, *m* vs. *racemic*, *r*) of the main chain, as is shown in Figure 2. Importantly, polymers with extended isotactic (...mmm...) or syndiotactic (...rrr...) trains usually crystallize, as the regularity allows long-range ordering of the chain molecules, resulting in material with very specific properties. The tactic sequences usually form regular helices, with polyethylene as the simplest case forming a 2_1 helix (2 monomers per 360° turn), corresponding to an all-*trans* structure. Owing to the γ -*gauche* effect, valuable information on the helical structure may be attained by high-resolution ^{13}C solid-state NMR. Atactic polymers usually do not crystallize (with poly(vinyl alcohol) as a prominent exception).

Four major factors determine the bulk properties of a polymer: the glass transition temperature (T_g), the tacticity, the degree of branching, and the monomer composition and distribution in the case of copolymers. Schematic structures are given in Figure 3. T_g is largely determined by the chemical structure, where as a rule of thumb, more rigid (e.g., aromatic or conjugated) backbone structures lead to a higher T_g . Stereoirregular linear homopolymers, highly branched structures, and random copolymers do not tend to crystallize well, and may either exist as a disordered melt above T_g or as a glass below T_g (such as plexiglas), the difference being the segmental mobility and thus the overall dynamics. Although a polymer melt may still be able to flow (depending on the molecular weight and the degree of branching), cross-linking of the chains (Figure 3(b)) leads to a shape-persistent material that is either elastic (above T_g) or rigid (below T_g), the latter being referred to as a thermoset. Most important polymer materials are

Figure 2 Different forms of tacticity of vinyl polymers made from a $\text{H}_2\text{C}=\text{CAB}$ monomer. Sequences of two or more stereocenters (diads, triads, tetrads, etc.) are referred to by their stereochemical diad succession, for example, mrrrr for the specific hexad example at the bottom.

Figure 3 Schematic structures of bulk polymers. (a) Melt or glass, (b) network, that is, elastomer or thermoset, (c) semicrystalline structure, (d) phase-separated (here lamellar) di- or tri-block copolymer. Polymer melts and glasses, and elastomers and thermosets, respectively, differ in their dynamics. Although rapid segmental as well as larger-scale motion is possible in the former, dynamics in the latter is restricted to local vibrations and side-chain motions (β , γ , ... subglass processes).

thermoplastics or thermoplastic elastomers, which flow and can be injection-molded at high temperatures, and are either rather rigid or elastomeric and shape persistent at ambient temperature.

Generally, even perfectly stereoregular, and thus crystallizable polymers never crystallize completely due to arrested kinetics associated with the necessary large-scale topological reorganization, leaving a material with rigid crystalline lamellae interleaved with a mobile amorphous phase (see **Figure 3(c)**). Consequently, these polymers are thermoplastics below the crystalline melting point, T_m . Thermoplastic behavior can also be achieved with block copolymers, in which chemically different subchains are connected by a bond. Chemically different polymers usually do not mix, and in the case of block copolymers, which exist as di-, tri-, or multiblock structures, the phase separation length scale is limited by the size of the chemically homogeneous blocks (usually a few tens of nanometers). This leads to a rich variety of possible nano- and microstructures (see **Figure 3(d)**), lamellae of a symmetric di-block being one example. If one of the blocks is below T_g at ambient temperature, the material is again a thermoplastic, as the rigid subphase acts as a cross-linker. From these examples, it is clear that the understanding of polymer materials requires structural and dynamic information over length scales from the molecular to the micrometer range, and dynamics from picoseconds (local vibrations) to seconds (flow, yield processes). NMR is essentially capable of covering these length and timescales, and it is thus a valuable tool providing atomic-level information that can complement many macroscopic property measurements.

In the following sections, the investigation of many of the above aspects by either solution- or solid-state NMR is addressed. The amount of literature on these subjects is vast, and while the authors have tried to cover what they consider the most important aspects, the choice of the presented topics is of course a matter of their personal preference. They have deliberately omitted pulsed gradient methods, as applied in diffusion or imaging studies of polymeric systems. Covering these fields is beyond the scope of this short contribution, and the authors refer the reader to specialized texts such as those of Kimmich and Blümich mentioned in the Further Reading section. The authors have also chosen not to cover multinuclear NMR using for instance ^{29}Si , ^{15}N , ^{31}P , and many other quadrupolar nuclei, which play an important role in the study of inorganic and functional polymers. It should be clear that the principles to be discussed here in relation to ^{13}C and ^2H are similarly valid for other heteronuclei. ^{19}F NMR is omitted as well, but it is certainly important for the characterization of many fluorinated polymers, and is also a wide field of its own. The acquisition of high-resolution solid-state ^{19}F spectra is a particular challenge because of its 100% abundance and high Larmor frequency, leading to

large dipolar line broadening similar to that of ^1H spectra, and the problem of heteronuclear decoupling from ^1H due to the closeness of the Larmor frequencies.

Solution-State Studies

The standard procedures of solution-state ^1H and ^{13}C NMR of small molecules may directly be applied to polymers, provided that a suitable solvent exists. Often, it is in fact not easy to prepare a polymer solution of sufficiently low viscosity, which is necessary to ensure rapid tumbling of the polymer coils as well as fast averaging over the different conformational states. Otherwise, broad lines or, for the case of fixed conformations, complex multiplet signals can challenge the interpretation of the spectra. In particular, solutions of high-molecular-weight polymers may be very viscous even under high dilution, requiring significant reductions of the concentration. Often, when the solvent is thermodynamically poor, the polymer tends to aggregate, again causing a broadening of the lines. Not uncommonly yet counterintuitively, the thermodynamic quality of a solvent can in fact decrease upon heating, such that increasing the temperature is not generally feasible. More serious solubility problems arise for block copolymers, where a common solvent for the different blocks must be found. Otherwise, the less soluble blocks aggregate, which leads to a highly viscous gel. Finally, cross-linked structures (elastomers) do not dissolve at all, but can only be swollen. In the latter cases, line-narrowing techniques adapted from solid-state NMR can, however, be used to obtain highly resolved solution-like spectra.

Chemical Identification and Molecular Weight Determination

Once a high-resolution spectrum can be recorded, the chemical identification is often straightforward. When the spectra are more complex than expected, the reason may be defects in a structure that was only assumed to be regular. For example, in vinyl polymers made from monomers of the type $\text{H}_2\text{C}=\text{CHR}$, the common head-to-tail arrangement ($\dots\text{CH}_2\text{---CHR---CH}_2\text{---CHR---}$) may be disrupted by head-to-head units ($\dots\text{CH}_2\text{---CHR---CHR---CH}_2\text{---}$), which are easily distinguishable by the chemical shifts of the involved nuclei, and their concentration is easily determined by integration. Similar arguments hold for the analysis of copolymer composition, where different modes of arrangement (different blockiness, e.g., $\dots\text{ABABAB}\dots$ vs. $\dots\text{ABAABABBB}\dots$) lead to correspondingly different and potentially complex spectra. In general, such NMR studies of the chemical microstructure are commonly used to elucidate details of the mechanism of the polymerization reaction. Other areas of applications are the study of polymerization kinetics by

real-time NMR, and of the chemical modification of polymers, for example, the substitution of side groups for property tuning.

An important aspect is represented by the chemically different and thus usually distinguishable end group signals. Provided that the polymer is linear or the degree of branching is known, integration of these signals and comparison with the main signals readily yields the degree of polymerization, and thus the molecular weight of the polymer (see **Figure 6** for a similar application). However, as the end groups comprise only a small fraction of the overall signal, the method is limited to low to intermediate molecular weights, with the upper cutoff being determined by the dynamic range of the receiver and the resolution of the analog-to-digital converter of the spectrometer. Note that nowadays, hyphenated techniques, such as the combination of size-exclusion chromatography and NMR, have become commercially available. They even allow for detailed chemical analyses of the different subspecies in polymer mixtures or, in particular, of samples with broad distributions of molecular weight.

Sequence Analysis

As explained in the first section, the proton or carbon chemical shifts of a polymer are sensitive to the stereochemical composition in much the same way as prochiral protons are distinguishable in small molecules. In polymers, such effects can be rather long-ranged (see **Figure 2**). Consider, for example, a vinyl polymer of the type $[\text{CH}_2\text{--CHR--CH}_2\text{--CHR--CH}_2\text{--CHR--}]_n$. It is relatively obvious that the methylene (CH_2) signal will mainly distinguish the relative stereochemistry of the CHR units left and right of it; it is thus sensitive to a single (m or r) diad structure, with potential fine structure caused by tetrads (e.g., mrm). In contrast, signals from the CHR group are mainly split by the triad structure (mm, mr, or rr), as both the central stereocenter as well as the adjacent monomer units contribute. The fine structure then differentiates pentads, or even heptads in favorable cases. The fine structure due to pentad sequences is highlighted in **Figure 4(b)** for the example of the methyl resonances of atactic polypropylene. Note that these microstructural effects on chemical shifts ultimately arise from different Boltzmann weights for different conformational states, which in turn depend on the bulkiness and position of different substituents. The experimental shift thus arises as a fast-limit average, and sufficiently fast conformational dynamics, that is, the use of lowly viscous solvent or high temperatures is vital.

Once the signals are assigned to different sequences, the integrated signal can again be used to gain important knowledge on the polymerization mechanism. For example, if only the probabilities of formation of m or r diads upon attachment of a new monomer to the growing

Figure 4 25 MHz ^{13}C NMR spectra of (a) isotactic, (b) atactic, and (c) syndiotactic polypropylene (PP: $-\text{[CH}_2\text{--CHCH}_3\text{]}_n-$). For the methyl groups in (b), the distinct regions of the different triad resonances are indicated, and the enlarged inset shows the resolution and assignment of pentad sequences. Reproduced from Tonelli AE and Schilling FC (1981) ^{13}C NMR chemical shifts and the microstructure of polymers. *Accounts of Chemical Research* 14: 233–238, with permission from the American Chemical Society.

polymer chain are different, the probability to find specific triads, tetrads, and so on, which is directly proportional to the corresponding relative signal intensities, can be readily calculated from Bernoullian statistics. If the probability to form an m triad is given by p_m , then $p_r = 1 - p_m$, and the triad probabilities are $p_{mm} = p_m^2$, $p_{mr} = 2p_m(1 - p_m)$, and $p_{rr} = (1 - p_m)^2$. Therefore, in such a case, the intensities of the triad signals must be explainable by a single parameter, p_m . If for chemical reasons, the attachment process is influenced by the stereostructure of a longer part of the chain end, a first- or higher-order Markov process determines the microstructure, and different independent conditional probabilities such as p_{m-r} are necessary to explain the intensity distribution. Obviously, the longer-ranged the influence of the chain end structure on the attachment process is, the more independent probabilities are involved, and the higher is the required n -ad resolution to determine all these probabilities.

Relaxation Studies

It is well known from classical Redfield and Bloembergen-Purcell-Pound (BPP) relaxation theories that T_1 and T_2 relaxation times (as well as nuclear Overhauser enhancements) depend on the spectral density of molecular

motion in the range of the Larmor frequency. In the case of polymers, solution-state relaxation studies therefore provide access to fast local segmental motions in the megahertz to gigahertz range, and to a limited degree also to the slower overall tumbling of the dissolved macromolecule as a whole. For the latter case, the relaxation data (relaxation times, preferably measured at different temperatures, Larmor frequencies, or both) can, for instance, be analyzed within the framework of the 'model-free' approach of Lipari and Szabo, originally established for proteins, which describes the dynamics in terms of two associated correlation times and an order parameter characterizing the spatial restrictions of the local segmental processes. More elaborate analyses

require the consideration of additional motional modes, or even more accurately, a full spectrum of relaxation times, as predicted by established theoretical models of polymer dynamics.

Since fast local motions dominate the T_1 relaxation times and are usually characterized by large-amplitude conformational jumps, it is possible to use relatively simple one-component BPP expressions to obtain at least approximate correlation times of these motions, and compare them among different polymers for qualitative insights into their local dynamics in solution. A prominent example is shown in **Figure 5** for the case of a specific class of macromolecules, namely dendrimers (or 'starburst' molecules), which are characterized by a

Figure 5 Investigation of dendrimer dynamics in solution by T_1 relaxation. (a) Schematic structure of a fourth-generation dendrimer and chemical structure of a PAMAM dendrimer, (b) ^{13}C T_1 relaxation times (at 75 MHz) of terminal and internal sites as a function of PAMAM dendrimer generation, and (c) derived motional correlation times. Parts (b) and (c) reproduced from Meltzer AD, Tirrell DA, Jones AA, et al. (1992) ^{13}C chain dynamics in poly(amido amine) dendrimers. A study of ^{13}C relaxation parameters. *Macromolecules* 25: 4541–4548, with permission from the American Chemical Society.

regularly branched structure, with the number of branches growing regularly as a function of chemical generation. Note that the end groups, either unreacted or modified in the last step, are chemically distinguishable from the interior of the molecule.

A long-standing debate in polymer science was the question whether the end groups of such tree-like structures cluster together in a dense outer shell, leaving cavities in the inside of the molecule (as implied by **Figure 5(a)**), or whether the arms eventually fold back, leading to a homogeneous distribution of more freely mobile ends throughout the structure. The correlation times for local segmental motions in **Figure 5(c)**, derived from the T_1 relaxation times in **Figure 5(b)**, both plotted as a function of generation, immediately proved that the latter is in fact correct: The terminal sites move much faster, which would not be possible if they clustered in a dense shell.

High-Resolution MAS Investigations

Finally, as mentioned above, the solution-state studies highlighted in this section are not limited to actual isotropic, molecularly disperse solutions. In fact, the only important requirement is fast local mobility of the

polymer, needed to achieve full conformational averaging. In many cases, the polymer in question may not be completely soluble, as is the case for block copolymers, aggregated systems in poor solvent, or most importantly, polymer networks. In all these cases, the polymer can only be swollen locally, that is, at least parts of the structure are surrounded by solvent and the segments move rapidly. On a larger scale, the tumbling of the respective substructure (aggregate, chain tagged to a surface of a network) is slow or even completely hindered. This leads to broadened spectra, where the line broadening arises from typical solid-state effects, that is, orientation-dependent interactions that are not averaged out completely, leaving on the solid-state scale a small, but potentially devastating residual broadening. Consequently, line-narrowing techniques from solid-state NMR, first and foremost magic-angle spinning (MAS), can be applied to very successfully remove this residual broadening and obtain spectra that are by and large comparable to solution-state spectra. This holds in particular for ^1H spectra, which are hard to obtain at high resolution in a truly rigid solid. Note that MAS cannot remove line broadening arising from true relaxation effects such as slow conformational exchange. In such cases, temperature variation is the only remedy.

Figure 6 NMR analysis of poly(dimethyl siloxane) (PDMS) elastomer formation via cross-linking of PDMS with methyl-vinyl-siloxane co-units and a difunctional silane cross-linker: (a) reaction scheme, (b) ^1H solution-state spectrum of the linear precursor polymer in CDCl_3 , and (c) ^1H MAS spectrum (4 kHz rotation frequency) of the bulk elastomer. The insets are vertically magnified by a factor of ~ 100 . For comparison, a static spectrum of octane-swollen PDMS is shown as a dotted line in (c).

For the investigation of soft solid systems, MAS probes with very good magnetic field homogeneity (shim) and thus good spectral resolution, and a deuterium lock system for field stabilization, have recently become available for solution-state narrow-bore magnets under the label HRMAS, for high-resolution MAS. Spinning frequencies of a few kilohertz are usually sufficient to obtain spectra of solution quality, and HRMAS has gained popularity for the investigation of membrane- or carrier-bound but locally dissolved, thus mobilized, biological macromolecules.

Even without elaborate shimming and a lock, simple slow-MAS ^1H spectroscopy, potentially using a cost-efficient narrow-bore MAS probe, allows for many fruitful applications in polymer science, and appears somewhat underestimated to date. An example is given in Figure 6, which shows solution-state and bulk-state MAS spectra of a vinyl-functionalized poly(dimethylsiloxane) precursor polymer, and the derived silicone elastomer after cross-linking with a bifunctional silane via a hydrosilylation reaction, respectively. Here, swelling of the elastomer to enhance chain motion is not even necessary, as the chains are very mobile (far above T_g) at room temperature. Figure 6(c) demonstrates that even the addition of solvent does not yield a spectrum with good resolution without MAS (dotted line), while the MAS spectrum is sufficiently resolved to identify all of the different functional groups. From this spectrum, the residual content of unreacted vinyl groups, as well as the content of $-\text{CH}_2-\text{CH}_2-$ cross-linking groups, is straightforwardly obtained by integration. Therefore, the average cross-link density, inversely related to the molar mass of the different network chains, can directly be obtained from such spectra. There is, in fact, no other direct method that serves this purpose, since networks and elastomers are per se nonsoluble; alternatives are thermodynamic (swelling), mechanical, or NMR relaxation measurements, all of which are indirect and require calibration or models.

Solid-State NMR

The major challenges posed by bulk polymers are that they are either at least two-phase systems (semicrystalline or block copolymers) or they undergo dramatic changes in their properties with temperature at around the glass transition. Amorphous phases below T_g and crystalline phases behave as rigid solids that require the full spectrum of methods from solid-state NMR, whereas soft melt-like phases (well above T_g) can in the NMR sense be treated as liquids, however with some residual solid-like properties. It is thus not uncommon that polymer scientists apply both solid- and solution-state experiments to their sample, to elucidate the potential

multiphase character or to infer the 'softness' of the material on a molecular scale.

Low-Resolution ^1H NMR

The simplest way to explore the multiphase character of a polymer system is to study its overall ^1H relaxation behavior, often simply reflected in the time-domain free-induction decay (FID), or by lineshape analysis after Fourier transformation. Proton spectra, by virtue of the strong orientation-dependent homonuclear dipolar

Figure 7 Low-resolution ^1H NMR of semicrystalline polymers and networks. couplings among the many abundant spins, with coupling constants on the order of 30 kHz for two nearby CH_2 protons, are very sensitive to molecular motion. Large-amplitude reorientations exceeding 10^5 kHz mark the transition into the soft, liquid-like domain, with substantially reduced couplings and thus narrower lines. In a semicrystalline polymer below T_m , with an amorphous phase well above T_g , a broad crystalline line (up to 50 kHz, due to multiple couplings) coexists with a narrower amorphous line ($\sim 10^2$ to 10^4 Hz), which in the time domain corresponds to a rapidly decaying crystalline contribution (~ 20 μs) and an amorphous part decaying in the milliseconds range. Simple decomposition into two components yields the approximate crystallinity in many cases. An example is displayed in **Figure 7(a)** for a measurement of syndiotactic polypropylene. Note that the detection of signal immediately after the excitation pulse is subject to a dead time problem (needed for pulse ring-down before detection can start), which must be overcome by suitable spin echo methods.

Such experiments are not restricted to semicrystalline polymers, but may also be of use for phase determination in phase-separated block copolymers or polymer blends, where the different components exhibit sufficient dynamic contrast. An important caveat is, however, the nontrivial, in most cases nonexponential, T_2 behavior in polymeric systems, leading to ambiguities in multi-component fits. The transverse relaxation behavior of a rigid system is almost Gaussian, because the decay is not a true motion-induced T_2 process, but rather a dipolar dephasing (dipolar couplings cannot be refocused by a simple Hahn echo). A more mobile, amorphous phase can exhibit any decay shape between a Gaussian and an exponential or even a stretched, multicomponent exponential, depending on whether the decay is dominated by residual dipolar couplings that arise from partially anisotropic chain motion or by the timescale of segmental fluctuations, respectively. Sample heterogeneity, such as mobility gradients, also plays a role here. This means that the apparent ' T_2 ' mostly has only heuristic value – the decay curves are hard to interpret quantitatively.

The relaxation behavior of networks or elastomers is usually completely dominated by residual dipolar couplings, as network chains are fixed at both ends and can never move isotropically. This is why T_2 in networks approaches a high-temperature plateau when heated sufficiently far above T_g , where the segmental motion is too fast to exert an appreciable influence. In this regime, the apparent T_2 is inversely proportional to the average residual dipolar coupling constant, which in turn is inversely related with the number of monomers in a network chain. An example is shown in **Figure 7(b)**. Therefore, T_2 results are directly related to the mechanical properties of elastomers, in that they provide molecular-level information on the cross-link density.

Yet, as stated above, a direct conversion requires many model assumptions. Nowadays, much more elaborate multiple-quantum experiments provide a more direct and quantitative means to not only measure residual dipolar couplings, but also assess aspects of its distribution. In this way, details on the microstructure of networks have become accessible.

The fact that a mesoscale motional anisotropy, leading to residual couplings, plays a role in such experiments means that they provide information on the chain dynamics on a semilocal scale. T_2 and related phenomena are thus not only useful for the study of elastomers, but also provide valuable tools to study, for instance, the dynamics of the amorphous/mobile chains in semicrystalline polymers or block copolymers, and of entangled polymer melts. Complementarily, the timescale and details of fast segmental motions are well in the 'liquid' range, and may be studied by T_1 relaxation, and in combination, polymer dynamics can be studied over several orders of magnitude in time. It should be noted that such experiments do not necessarily require superconducting high-field spectrometers – cost-efficient, low-field equipment is often fully sufficient, as the effects in question are based on dipolar couplings and are thus field independent. This of course only holds if chemical resolution is not necessary.

Naturally, the low-resolution assessment of phase composition in any heterogeneous polymer system is critically based on sufficient mobility contrast. If, for instance, the amorphous phase of a semicrystalline polymer is not mobile enough, and temperature variation would alter the structure or the morphology, high-resolution ^{13}C spectroscopy is inevitable.

High-Resolution ^{13}C NMR

High-resolution ^{13}C NMR spectroscopy in solids is commonly achieved by MAS in combination with high-power dipolar decoupling (DD) and cross polarization (CP). MAS and DD provide spectral resolution, that is, they split up the wide and, in polymers, often featureless powder line shapes into relatively narrow lines. Although MAS-DD spectra often do not reach the line resolution of solution-state spectra (the line width in solids is on the order of few parts per million, whereas in liquids it is typically down to 0.1 ppm), they still provide useful spectral information. First, the larger line width is often due to distributions in conformations; thus it carries information on disorder. In fact, the ^{13}C lines of crystalline phases in semicrystalline polymers are often almost as narrow as solution-state lines. Second, the line width must be considered in relation to the overall chemical shift range of approximately 200 ppm and compared with the very limited resolution of ^1H solid-state spectra, which – even under very fast MAS or multipulse line

narrowing – exhibit line widths on the order of 1 ppm on a chemical shift scale of only approximately 10 ppm.

CP, on the other hand, permits a substantial shortening of the experimental time, as it produces a stronger signal (theoretically up to a factor of 4 for ^{13}C , practically between 2 and 3, as compared to direct ^{13}C excitation) and permits a shorter repetition time between subsequence signal averages due to its dependence on the shorter ^1H T_1 , which is approximately one order of magnitude shorter than the ^{13}C T_1 , which in turn governs the repetition time of directly excited ^{13}C spectra. MAS and DD had already been combined with CP in the 1980s, and still represent the major methodology for almost all solid-state ^{13}C experiments. A comparison of CP spectra with DD (removing dipolar couplings), with and without MAS (removing the ^{13}C chemical shift anisotropy), is presented in Figure 8. The dramatic increase in resolution (accompanied by a large time saving) is readily apparent.

Although, owing to the limited resolution, information on the monomer sequence is hard to obtain from

solid-state spectra, supramolecular structural features such as amorphous or crystalline phases are more easily recognizable. Usually, chemical segments in the crystalline phase are more rigid or they feel a chemically similar environment, leading to relatively narrow lines, whereas segments in the amorphous phase are in a disordered environment, leading to a distribution of isotropic chemical shifts and broad lines, which might additionally be subject to dynamic broadening. Thus, depending on temperature, the molecules exhibit a molecular mobility in the kilohertz range, which interferes with the line narrowing by MAS and DD and leads to temperature-dependent line broadening. As an example, Figure 9 shows the structure of the crystalline phase of a specific semicrystalline polyolefin, the crystallite chains of which form 7_2 helices. The broad bases of the lines in the ^{13}C CPMAS spectrum (dotted ellipses) arise from contributions of the amorphous phase, which can be suppressed by a relaxation filter.

The authors would like to draw the attention to a comparison between the inset of Figure 7, where the amorphous and crystalline components were assigned to the narrow and wide proton subspectra, respectively, and the just explained reversed assignment in the carbon spectrum. The apparent contradiction can be understood on the basis of the dynamic properties of the different phases and the different origins of line broadening in ^1H and ^{13}C spectra: the molecules in the crystalline phase are rigid and experience a large ^1H - ^1H dipolar coupling, resulting in a wide ^1H spectrum that is almost entirely governed by this interaction, whereas the higher mobility of the molecules in the amorphous part partially average this coupling, resulting in a narrower line. This assignment is generally valid, and challenged only in cases where T_g of the amorphous phase is not low enough to render it sufficiently mobile.

In ^{13}C spectra, however, the dominant interaction is the isotropic chemical shift of the carbons, since the anisotropic chemical shift as well as the dipolar couplings are (usually) efficiently suppressed by MAS and DD. Thus, the line widths are determined by the degree of order of the local environment of the probe nucleus, explaining the reversed assignment.

This component assignment in ^{13}C spectra is, unfortunately, not unique. In unfavorable cases, amorphous and crystalline line widths and positions can in fact be hardly distinguishable. A particularly unusual case is poly(ethylene oxide), where the assignment of the room temperature ^{13}C spectrum is again reversed, as the crystalline resonance is extremely broad due to intermediate (kilohertz) mobility of the chains in the crystallites (helical jumps) that interfere with the decoupling and MAS (details on such motional broadening effects are addressed in the next section). In addition, the crystalline helix in this polymer is disordered, such that the

Figure 8 ^{13}C CPMAS spectrum of poly(*n*-butyl methacrylate): (a) nonspinning and (b) under MAS condition with a spinning rate of 4 kHz. Note that in (a), the resonances of the aliphatic carbons overlap, whereas they are well resolved in (b). Also, the powder pattern of the carboxyl resonance is well recognizable in the static spectrum, due to its large high frequency (deshielded) shift and the large chemical shift anisotropy. The information about the chemical shift anisotropies still appears in the MAS spectrum in the form of spinning sidebands (*).

Figure 9 ^{13}C CPMAS spectra of poly(4-methyl-1-pentene). (a) The 7_2 helical structure of the crystallites (view down the c axis). (b) CPMAS spectrum and resonance assignment. (c) Separation of amorphous and crystalline signals by a $T_{1\rho}$ filter at two temperatures. The spin-lock times τ_{CP} are 0.01 ms for the full spectra, containing both components, whereas longer τ_{CP} times (10 ms at 299 K and 4 ms at 488 K) allow the signals from the amorphous molecules to relax away, leaving only the signals from the crystallites (dotted lines). The difference spectra contain the amorphous signals only. Reproduced from Miyoshi T, Pascui O, and Reichert D (2004) Slow chain dynamics in isotactic-poly(4-methyl-1-pentene) crystallites near the glass transition temperature characterized by solid-state ^{13}C MAS exchange NMR. *Macromolecules* 37: 6460–6471, with permission from American Chemical Society.

line remains ~ 3 ppm broad even at low temperature when the chain motion is slowed down. From this example, it could be noted that complex motional effects and other origins of line broadening may always contribute to the line widths of carbon MAS spectra of polymers, and must be carefully considered and explored, for example, by temperature variation.

Given the lack of or an ambiguity in spectral distinction between different phases or components, their separation can be aided by relaxation-time filters that are based on different mobilities. The easiest of these is a simple change in the repetition delay between subsequent scans for signal averaging (corresponding to a ^1H T_1 filter when CP is used, or a ^{13}C T_1 filter in case of direct excitation). A good general way to explore coexisting mobile amorphous and rigid crystalline or glassy regions (in semicrystalline polymers or block copolymers, respectively) is to simply compare ^{13}C direct excitation spectra with repetition delays on the 1 s timescale (emphasizing mobile amorphous regions), and CPMAS spectra with short CP (emphasizing rigid regions). Other possibilities are, for instance, using the different $T_{1\rho}$ of either ^1H or ^{13}C by changing the CP spin-lock time, or exploiting T_2 differences by adding Hahn echo delays on either channel (either before or after the CP). An example of a $T_{1\rho}$ filter procedure for component separation in a semicrystalline polyolefin is presented in Figure 9(c).

Multidimensional ^{13}C NMR

It is obvious from the above that in solid-state ^{13}C spectra, the structural information (provided by the isotropic chemical shift value) is often concealed by dynamic information, which arises from different degrees of

averaging of anisotropic interactions by molecular motions. Such interactions are the anisotropic chemical shift and the homo- and heteronuclear dipolar coupling, as well as the quadrupolar coupling when nuclei with $I > 1/2$ are measured (this will be addressed in the next section). Basically, all these interactions (except the quadrupolar coupling) contribute to the appearance of the ^{13}C spectrum and in principle, the spectra can be simulated to determine the different contributions and to extract the desired information. Note that even indirect couplings, such as ^1H - ^1H homonuclear dipolar couplings, affect ^{13}C spectra in a way that they interfere with the efficiency of DD and increase the line width.

However, in particular under conditions of finite signal-to-noise and due to the large number of potentially involved spins and the complex dynamics, full spectral simulation is in practice almost impossible. Instead, it is desirable to separate the different effects in different (spectral or time) dimensions of multidimensional experiments. The probably simplest example is the acquisition of ^{13}C CP spectra as a function of the above-mentioned relaxation filter durations, incremented in regular intervals. One can then achieve a component decomposition of the spectrum and at the same time estimate the respective relaxation times.

Turning to ‘true’ 2D spectroscopy, such experiments can, for instance, correlate the isotropic chemical shift in one dimension with the anisotropic chemical shift or heteronuclear dipolar coupling in a second dimension. The latter are termed ‘separated local field’ (SLF) experiments, and are among the most popular approaches, because they are robust, easy to implement and require standard hardware only. Last but not least, the heteronuclear dipolar interaction is well defined (as it reflects

the arrangement of heterospins in the immediate surroundings of the nucleus) and thus easy to interpret. A particularly simple and correspondingly popular sequence is the so-called WISE (wideline separation) experiment, which is not strictly an SLF experiment, but similar to it, in that it correlates the carbon CPMAS spectrum with the ^1H wideline spectrum of the protons closest to the carbon. The pulse sequence is identical to the CPMAS sequence with a short CP time (for local transfer), with the only difference that an incremented delay is inserted between the first ^1H pulse and the CP spin lock, during which the ^1H FID is probed. The pulse sequence, as well as typical proton and carbon spectra along with their separation in a 2D WISE spectrum, is depicted in **Figure 10**.

As mentioned already in the preceding section, a very simple alternative and the most recommendable first approach to assess dynamic heterogeneity is to compare CP spectra acquired with rather short contact times (polarizing only rigid, strongly dipolar-coupled ^{13}C) with one-pulse direct-polarization spectra taken with a short recycle delay on the order of a few seconds (emphasizing signals from highly mobile liquid-like ^{13}C with correspondingly short T_1). With such experiments, or by comparing the wide or narrow lines in the proton dimension of 2D WISE spectra, it is very easy to distinguish carbons from rigid and mobile domains. However, even from the resolved proton line shapes, it is difficult to draw truly quantitative conclusions, since the homonuclear ^1H - ^1H coupling involves many nuclei and the spectra are hard to simulate correctly.

More elaborate, true SLF experiments utilize ^1H homonuclear decoupling, which leaves the ^{13}C - ^1H dipolar interaction as the only remaining coupling for the second dimension and thus, provide a much clearer picture. Examples are the DIPSHIFT (correlation of dipolar and chemical shift information) and LG-CP (Lee-Goldburg cross polarization) experiments. The latter is in fact just a more quantitative version of the traditional CP experiment, in which the ^{13}C - ^1H dipolar coupling is extracted from the intensity buildup as a function of the variable CP time. Such experiments are also particularly suited for the quantitative measurement of residual heteronuclear dipolar couplings, as addressed below.

Dynamic and Exchange NMR

As already alluded to, indirect structural information can also be inferred from dynamic data, for example, from the different mobility of molecules residing in amorphous or crystalline phases. Thus, and in particular due to the fact that many mechanical properties depend crucially on the molecular mobility of the polymer chains, it is desirable to determine the kinetic parameters quantitatively, that

Figure 10 (a) Pulse sequence of the WISE experiment. Typical magnetization decays are shown for mobile (full line) and rigid components (dotted line). (b) ^1H (left) and ^{13}C spectrum (right) of a 1:1 blend of poly(styrene) and poly(vinyl methyl ether). The ^1H spectrum is the superposition of wide and narrow components that originate from the different polymers, due to their different mobilities. They cannot be distinguished here, whereas in the ^{13}C spectrum the resonances of the two polymers are well separated. These two different sets of information can be nicely separated in the 2D WISE spectrum (c). Reproduced from Schmidt-Rohr K, Clauss J, and Spiess HW (1992) Correlation of structure, mobility, and morphological information in heterogeneous polymer materials by two-dimensional wideline-separation NMR spectroscopy. *Macromolecules* 25: 3273–3277, with permission from John Wiley & Sons Ltd.

is, both amplitudes and time constants. Molecular dynamics in polymers spans a wide range of correlation times, from very fast processes on the order of pico- and nanoseconds, up to slow motions on the order of milliseconds or even seconds. To cover this entire range, different techniques have to be applied.

For fast processes, relaxation techniques as explained in the Solution-State Studies section can be employed. Additionally, the measurement of partially averaged anisotropic couplings is particularly informative in this regime, as in solids or soft semisolids (such as glassy or rubbery polymers), and in contrast to the liquid state, anisotropic motions do not average the interactions completely, even though they may be very fast. The degree of averaging depends on the amplitude of the motional process and is commonly parameterized by a so-called dynamic order parameter, which is just the ratio of the measured, partially averaged coupling to the value for a completely rigid segment, that is, the full coupling. For specific models, the order parameter can be recast into amplitudes of motion; however, in most cases, the order parameter itself, and its temperature dependence or the comparison between different samples, provides useful information.

So-called intermediate motions with correlation times in the microsecond range can be easily recognized from the temperature dependence of the carbon spectra, as the molecular process occurs on the timescale of the lifetime of the NMR signal (as reflected in the T_2 relaxation time, or the decay time of the FID). In combination with high-resolution line-narrowing techniques such as MAS or DD, it has to be kept in mind that these remove contributions from the anisotropic chemical shifts or dipolar couplings by modulating the spin interactions (either in real space or in spin space, respectively) with a typical frequency (the MAS rotation frequency or the nutation frequency of the ^1H irradiation, respectively). Now, if the inverse of the correlation time of the molecular motion approaches these modulation frequencies, the efficiency of the line-narrowing mechanism deteriorates and a so-called dynamic line broadening appears, permitting a simple qualitative assignment of a correlation time to the inverse modulation frequency at the temperature at which the maximum broadening appears.

More quantitative information can be obtained from the comparison of calculated/simulated spectra with experimental ones, and the application of SLF experiments in this dynamic range. However, the by far most accurate approach for intermediate motions is the acquisition of ^2H spectra and the comparison with calculated line shapes. These experiments have an inherently low resolution, as the lines are very broad (but well structured), and the price to pay is the effort in the preparation of selectively ^2H labeled substances, in order to study the motional processes with molecular resolution. On the positive side, the ^2H quadrupolar interaction as the dominant spin interaction is an extremely local and well-defined dynamic probe, as it is merely sensitive to orientations of the (asymmetric) local electronic environment of the nucleus, and the spectra can therefore be simulated rather accurately. This is

demonstrated in **Figure 11** for local motions in glassy poly(carbonate), where the different chemical groups have been labeled and studied separately. The thus-quantified phenyl flip motion is in fact an important contributor to the efficient dissipation of mechanical energy in this high impact strength polymer.

On the slow end of the dynamic range of NMR experiments are the so-called exchange experiments, which are capable of detecting molecular reorientations that occur on timescales much longer than T_2 . Such motions do not lead to notable spectral changes. Exchange NMR relies on the fact that molecular orientations are encoded in NMR frequencies via anisotropic interactions, and that any change in molecular orientation results in a change in the resonance frequency of the probe nucleus, in principle on any timescale. A technique that can detect these frequency changes can thus be used to detect such

Figure 11 Observed and calculated ^2H spectra of selectively deuterated polycarbonate. The methyl deuterons exhibit for both temperatures the typical spectrum of a rotating methyl group with a quadrupolar coupling constant that is reduced by a factor of 3. At room temperature, the spectrum of the phenyl ring corresponds to a deuteron attached to a fast flipping ring, whereas at higher temperature, an additional small-angle motion of the polymer chain contributes to reducing the line width and changing the shape. Reproduced from Spiess HW (1983) Molecular dynamics of solid polymers as revealed by deuteron NMR. *Colloid and Polymer Science* 261: 193–209, with permission from Springer-Verlag GmbH.

dynamic processes. The general principle is always that after measuring the interaction frequency (= orientation) during an evolution delay, the magnetization is stored along the magnetic field axis (along z) by a 90° pulse. It is then read out again after a mixing time that is limited only by the (often very long) T_1 relaxation time, and a second frequency measurement (most often just a spectrum acquisition) follows right after.

These experiments are therefore most often two-dimensional: NMR data (FIDs) are sampled in two time dimensions that are separated by a freely chosen mixing time, during which the molecular dynamic process can occur. A two-dimensional Fourier transform correlates the data from the two time domains in a 2D spectrum, and whenever a process has changed the molecular orientation, peaks off the main diagonal of the spectrum immediately reveal the dynamic process. The widespread application of such methods started out in the 1980s, with applications of ^2H - and ^{13}C -chemical-shift anisotropy-based methods, prominently by the Spiess group, and MAS variants for ^{13}C samples in natural abundance. An example for the former is shown in **Figure 12**, where the more complicated phenyl ring motion in poly(styrene) is elucidated by 2D ^2H exchange methods on the slow (low-temperature) end, and is complemented by information from other dynamic NMR experiments in order to characterize the process over almost 10 orders of magnitude in time. It should be noted that the off-diagonal intensity distribution in the 2D spectra sensitively encodes the reorientation angle, which is in this case distributed over a wide range, as the underlying process corresponds to rotational diffusion.

On the down side, the 2D acquisition scheme renders the 2D approach rather time consuming, and as one of the most recent improvements, the so-called CODEX sequence, illustrated in **Figure 13**, was established as an easy-to-implement and robust one-dimensional MAS method that permits the reliable determination of both the correlation time of motion as well as its amplitude in natural isotopic abundance samples. In this high-resolution 1D method, the sampling of the time-domain signal in the indirect dimension is replaced by a fixed evolution time during which the magnetization can acquire a certain phase, arising from the anisotropic chemical shift (CSA) frequency, thus encoding the molecular orientation. The same is done after the mixing time, and the signal intensity in the highly resolved ^{13}C spectrum finally depends on whether the nucleus in question along with its anisotropic shielding environment has rotated or not. The 180° pulses during these periods manipulate the acquired phase, in a sense that they actually reverse the averaging by MAS (which would in principle preclude the CSA measurement, see **Figure 8**). This is called 'recoupling' and represents a very general technique often applied in solid-state MAS NMR. The

Figure 12 (a) Experimental and (b) calculated 2D exchange ^2H spectra of chain-deuterated poly(styrene) (PS) at 391 K and a mixing time of 6 ms. The calculated spectrum is generated on the basis of an isotropic rotational diffusion model with a log-Gaussian distribution of correlation times (width ~ 3 decades, centered around 6 ms), and the corresponding jump-angle distribution is shown in the inset. (c) Arrhenius plot of the mean correlation times for PS resulting from different experiments, with a common Williams-Landel-Ferry fit to the data describing the temperature dependence of the α process associated with the glass transition. Transition to motional averaging and application to the glass transition. *Journal of Chemical Physics* 93: 197–214, with permission from American Institute of Physics.

Figure 13 Pulse sequence and data of the 1D MAS exchange experiment CODEX, as applied to slow motions in the crystalline phase of the same polyolefin as in **Figure 9**. (a) Pulse sequence (^{13}C channel only). The essential parts are the mixing period t_m , which is sandwiched between two recoupling cycles, applying trains of rotor-synchronized π -pulses. (b) To extract the correlation time of motion, the number of recoupling cycles is kept constant while the length of the mixing period t_m is incremented logarithmically. The longer the t_m , the more molecules perform a reorientation, leading to signal decay. The straight line is a fit to a stretched exponential function yielding the average τ_c . (c) For information on amplitude of motion, t_m is kept constant at a value larger than τ_c and the number of recoupling cycles is incremented. For more details, see Miyoshi T, Pascui O, and Reichert D (2002) Helical jump motion in isotactic-poly(4-methyl-1-pentene) crystallites revealed by 1D-MAS exchange NMR spectroscopy. *Macromolecules* 35: 7178–7181.

length of the evolution/recoupling time necessary to observe the exchange process is in fact a quantitative measure of the motional amplitude, and actually provides an even better sensitivity for small-amplitude motions as compared to traditional static 2D exchange spectroscopy.

Spin Diffusion NMR

Truly structural methods are the so-called spin diffusion experiments, which can be used to determine domain sizes in materials that are not suited for scattering studies (e.g., by missing long-range order). Spin diffusion is an effect driven by homonuclear dipolar interactions between abundant spins, mostly protons, by which magnetization is transported between spatially fixed spins over distances as large as some 100 nm by a quantum-mechanical flip-flop process. It can in fact be measured with the same one- or two-dimensional versions of exchange spectroscopy mentioned above, just because spin diffusion occurs on similar, rather long timescales between the z components of differently polarized spins. Spin diffusion is often a competing process to dynamic exchange, and temperature variation can be used to distinguish between the two: spin diffusion is only weakly temperature dependent, and if at all, the process becomes slower with increasing temperature, due to dynamic averaging of the dipolar interaction that is responsible for it.

τ_A typical experimental scheme is shown in **Figure 14**. Two phases A and B that can be discriminated by their NMR parameters (e.g., crystalline and amorphous), in this case by the resonance frequencies, contribute to the NMR spectrum. By a selection process that can be realized either by selective excitation or the application of relaxation filters or dipolar filters, a single component (in this case A) is selected. Then the magnetization is permitted to spread by spin diffusion throughout the sample during a mixing time, and eventually, the polarized B spin signal reappears in the spectrum. Given a dynamically heterogeneous multiphase structure, such experiments can in fact be performed under low-resolution conditions (see **Figure 7**), using the mobility contrast both for the phase-specific selection of magnetization, as well as for the component-specific detection.

The experiment is repeated for different mixing times, and the increase of the B component or the decay of the A component yields information on the domain sizes, provided the NMR parameters (i.e., the spin diffusion coefficients) and the overall structure of the phases (1D diffusion in a lamellar system vs. 2D diffusion among cylinders, etc.) are known. Another distinguishing factor is that spin diffusion is described by a square-root-of-time law in its initial stages (cf. the Einstein-Smoluchowski equation), whereas a dynamic exchange process follows an exponential rate law, which is linear in the early stage.

Figure 14 (a) Schematic representation of ^1H spin diffusion in a two-phase system with spatially constant proton density. After the selection period, protons are polarized only in one phase A, and the NMR spectrum only shows the corresponding signals. The redistribution of magnetization by ^1H spin diffusion is monitored in the spectrum: with increasing mixing time, the intensity of signals corresponding to the selected region A decreases, whereas the signal intensity of the initially depleted region B increases. (b) Spin diffusion diagrams as obtained for different PS-PMMA block copolymer samples. The values at the simulation curves indicate the long periods $d_a + d_b$. Reproduced from Clauss J, Schmidt-Rohr K, and Spiess HW (1993) Determination of domain sizes in heterogeneous polymers by solid-state NMR. *Acta Polymerica* 44: 1–17, with permission from Wiley Interscience.

Thus, a linear behavior in a plot of the intensity versus the square root of time reveals a spin diffusion process, and the initial slope encodes the size of the domain, as is apparent from Figure 14(b).

Oriented Polymers

Last but not least, it is possible to make use of the orientation dependence of the NMR resonance frequency to obtain information on molecular orientations in

anisotropic polymeric systems such as stretched polymers or fibers. Since the resonance frequency of a nucleus is – for anisotropic interactions – determined by its orientation versus the external magnetic field, it is obvious that the distribution of orientations immediately shows up in the solid-state NMR spectrum. Such studies are limited to samples where dynamic effects on the spectra are absent, that is, the samples are either completely rigid (e.g., cooled below T_g), or motions that are present must be anisotropic and in the fast limit (e.g., methyl rotation or phenyl flips).

The principle of the approach is illustrated by perfect powder spectra ('Pake' patterns) such as the CSA pattern of the carbonyl carbon in **Figure 8(a)** or the quasi-static (pre-averaged) ^2H spectrum of the methyl group in **Figure 11**, which only arise if the distribution of different orientations in the sample is completely isotropic. Any such prototypical solid-state spectra become distorted once a macroscopically oriented or otherwise ordered sample is measured: if not all orientations are present with the same probability, the deviations of the spectral shape from the Pake pattern arise and allow for a quantitative extraction of the orientation distribution. Even better quantification is possible if spectra with different orientations of the magnetic field with respect to the sample axes (e.g., the stretching direction) are acquired and analyzed simultaneously. A limiting case is represented by liquid-crystalline systems, which often orient perfectly in the magnetic field, or simply by single-crystal samples, where the Pake spectrum is reduced to a single line (or a single splitting), corresponding to a single orientation. Observing and analyzing spectra at different sample orientations is often referred to as 'NMR crystallography'.

As is also obvious from the two figures addressed, again, ^2H is the most useful nucleus for such investigations, since the quadrupolar interaction is strictly local, large, and dominant (whereas the CSA spectrum can be broadened by imperfect decoupling, conformational disorder, etc.). Further, the orientation of the quadrupolar symmetry frame is in good approximation parallel to the chemical bond that connects the deuteron to the rest of the molecule, rendering a quantitative interpretation of the orientation distribution rather straightforward. Again, the price to pay is the synthetic effort to label the polymers with ^2H . However, multidimensional (recoupling) MAS

methods, which work for ^{13}C in natural abundance, have also been applied for this purpose. In this case, numerical procedures to extract structural information from the intensities of specific spinning sidebands are needed, and are often less quantitative than fits to perfect static ^2H spectra.

Polymorphism Studied by Solid-state NMR

Robin K Harris, University of Durham, Durham, UK

© 2010 Elsevier Ltd. All rights reserved.

Introduction

Polymorphism is a very widespread phenomenon in chemistry. It commonly occurs in both organic and inorganic chemistry and in mineralogy, and is also found for polymers and biochemicals. However, it is not straightforward to define it precisely. McCrone's first definition of polymorphism, which is frequently quoted, is the ability of any element or compound "to crystallize as more than one distinct crystal species." This definition, though useful, is inadequate to describe the range of related aspects, and terminology in this area can be confusing. McCrone's second definition of polymorphism is perhaps more useful: "A polymorph is a solid crystalline phase of a given compound resulting from the possibility of at least two different arrangements of the molecules of that compound in the solid state." However, this refers only to molecular, as opposed to network, polymorphs. Other terms can be used for particular types of polymorphism. Thus, for elements, allotropy is the normal description, and is used in cases that would not be recognized as polymorphs under a strict definition of polymorphism (e.g., diamond, graphite, and C_{60} , for which the bonding is so different that they can be best regarded as different compounds). (In fact McCrone spoils his first definition of polymorphism by giving diamond and graphite as an example. His second definition would founder for these cases anyway, since there is no distinguishable 'molecule' in diamond or graphite.) For certain types of structure with repeated planes of atoms, differently stacked (such as silicon carbide), the name polytypism is used.

In addition, many systems do not quite fit into a simple pattern of different crystal structures for identical chemical compounds. Thus, hydrates (or in general solvates) are often referred to as pseudopolymorphs (of the anhydrous compound), though this term is to be deprecated. In fact, a stoichiometric solvate is not a polymorph of any anhydrous form, but of course a particular solvate composition may itself exist in polymorphic forms. However, a monohydrate and a trihydrate of the same compound are not polymorphs. On the other hand, the relationship of solvate structures to those of anhydrous forms is of considerable interest, especially in the pharmaceutical industry, since some of the latter may be best (or only!) obtained via the former. NMR can, of course, be of great value in studying crystal structures of both polymorphs and solvates (and, indeed, cocrystals, which can be seen as solvates with both components solid

at ambient temperature). McCrone's definition is also debatable insofar as the solid state can be more complex than a simple division into crystalline and noncrystalline implies. Disordered or nonstoichiometric systems have an impact on matters related to polymorphism. Some forms recognized as polymorphs may only be stable when a small (nonstoichiometric) amount of a solvent is present. Moreover, even amorphous systems can exist in different forms, which may be termed polyamorphs, for example, from different preparations such as grinding a crystalline form or flash-cooling from a melt or a solution. However, there is clearly an infinite number of amorphous structures of a given compound. In consequence, some authors use the word 'form' to refer to amorphous situations or solvates, while using 'modification' to refer different crystalline structures for identical chemical compounds.

At a structural level, polymorphs can be divided into a number of categories. There are, for example, molecular polymorphs (e.g., of medium-sized organic compounds) where intermolecular forces (such as hydrogen bonds) or molecular shape may dictate the possible ways in which unit cells can be constructed. At the other extreme, there can be three-dimensional network systems (such as the already-mentioned silicon carbide) where no separate molecules can be identified. In the molecular cases, some forms differ mainly in the conformation adopted – these are appropriately known as conformational polymorphs – whereas in other cases the differences are largely in the packing of molecules whose individual shapes remain essentially the same.

Whatever the nature of polymorphism, the polymorphs differ in every physical property, for instance, melting point (sometimes difficult to observe because transformation into a different form intervenes), solubility, infrared spectrum, and so on (though on occasion the differences may be too small to detect). This fact extends to the NMR spectrum. The differences in NMR spectra between polymorphs may be small (even undetectable) to large, depending on the variations in structure involved and on the nuclide observed. The inverse of this principle means that NMR can be of significant help in understanding the structure, both molecular and crystallographic, of the various forms, as discussed in the following text. Thus, the NMR study of polymorphism may be considered as a branch of the increasingly important subject of NMR crystallography, which can be the key to obtaining crystal structures, with NMR usually used in combination with diffraction

methods. NMR is also often vital in establishing the mobility of chemical groupings in crystalline solids, a topic that is difficult for diffraction techniques to address.

In addition to the obvious questions of structural differences between polymorphs, the nature of transitions between them is often of great interest. Under any particular set of conditions (temperature, pressure, etc.) only one modification will be stable. However, the barrier to a transition from an unstable (or metastable) form to the stable modification may be very high. It is clear that, in general, phase transitions between molecular polymorphs will be much easier than for many network polymorphs, which require bond breaking and reforming (reconstructive transformations). Unstable (or, rather, metastable) molecular polymorphs can often be prepared from solution, from the vapor phase, from desolvation, or by rapidly cooling from the melt.

Under normal pressure, some phase changes between polymorphs may be accomplished reversibly by temperature variation (in which case the modifications are said to be enantiotropically related), but in other cases, this is not possible and a form may be unstable (metastable) with respect to another over the whole temperature range (monotropic polymorphism). Although the phase changes for enantiotropic molecular polymorphs are in principle reversible, they are often accomplished by significant hysteresis. This arises, in part, because, at the transition temperature, the rate of polymorphic change is at a minimum – there is no free energy difference between the forms to drive the reaction. Most transitions between molecular polymorphs involve a breakup of the original crystal structure with re-formation into a new structure. However, in a minority of cases, the change is single-crystal to single-crystal – usually a rapid process involving little or no hysteresis. NMR can, of course, monitor phase changes, and can also, in favorable circumstances, measure rates of transformation.

The NMR techniques used to study polymorphs are basically the same as those employed by solid-state NMR in general. Therefore, they will not be discussed herein, but rather the emphasis will be on describing the variety of results that can be obtained.

Structural Characterization

Identification

The atoms in polymorphs have different spatial arrangements of their neighbors, both bonded and nonbonded, in spite of the fact that the intramolecular bonding itself is the same in nature. This means that the analogous atoms in different polymorphs will, in principle, have different chemical shifts. In other words, the spectra of polymorphs differ characteristically and so may be used as ‘fingerprints’ to identify each modification. This is illustrated in

Figure 1 for phenobarbital (1), which is typical but with some special characteristics – several anhydrous modifications have been reported. **Figure 1** shows the ^{13}C spectra of forms I, II, and III, the crystal structures of which are known from diffraction measurements.

Two facts are immediately apparent. The first is that, whereas form III has a single peak for each carbon in the system (with some overlap), forms I and II have many more. The resonance for the methyl carbon C-5 constitutes a clear triplet in these cases (as do some of the other signals) and it can be immediately concluded that there are three molecules in the crystallographic asymmetric unit for modifications I and II, whereas there is only one such molecule for modification III. This conclusion is in agreement with the crystal structures. Obviously, in cases where the crystal structure is not known, such NMR-derived information can be very helpful in the analysis of single-crystal (or, even more vitally, powder) diffraction data. The second feature of interest in the spectra is the very close similarity of the shifts for modifications I and II. This is a relatively unusual circumstance, especially given that the crystal structures differ not only in space group but even in crystal system (form I is monoclinic and form II is triclinic). (This contrasts with the more usual case, where NMR is actually more sensitive to small polymorphic differences than diffraction.) However, the crystal structures are closer than they might appear to be, since in both cases the angles between the unit cell axes are close to 90° and deviate by less than about 2%. Moreover, the lengths of the unit cell sides a and c are close in value, whereas that of b for form I is close to twice that of form II. However, detailed reasons for the specific differences between the signals for forms I and II (for instance, for C-4) remain obscure.

One of the advantages of NMR for characterizing polymorphs is its multinuclear nature. For phenobarbital, it is not difficult (using an overnight run) to obtain reasonable-quality ^{15}N spectra, as shown in **Figure 2**.

The appearance of six lines for forms I and II, but only two for form III, is consistent with the number of

Figure 1 Carbon-13 CPMAS spectrum at 100.6 MHz of phenobarbital (1). Top: polymorph I; middle: polymorph II; and bottom: polymorph III.

molecules in the asymmetric unit. Moreover, forms I and II give closely similar spectra – but again they are sufficiently different to show that two different forms are involved.

The full chemical shift tensors of polymorphs may differ in a more sensitive fashion than the isotropic values. This has been shown to be true, for example, for two polymorphs of dimethyl-3,6-dichloro-2,5-dihydroxyterephthalate (2), especially for the ester carbon, for which the isotropic shifts are almost indistinguishable, but two of the principal values differ significantly (by 9 and 11 ppm, in opposite directions).

Inorganic examples of polymorphism abound, particularly under a relatively relaxed definition of the term.

Silicon carbide is a typical example of a special area of network polymorphism known as polytypism. All silicon atoms are tetrahedrally coordinated to carbon and vice versa. However, if one considers 'layers' of SiC, these can be superimposed in different ways (i.e., with different offsets), leading to different numbers of SiC atom pairs in the asymmetric unit. Form 3C, for example, has successive layers offset in the same sense, giving a unique environment for the silicon atoms (or carbon atoms). The layers for the 2H form alternate in offset, again giving a single SiC environment. However, the stacks for form 4H have offsets that reverse every alternate layer (giving a structural repetition which can be described as ...BCBCBC...), whereas those of the 6H form repeat as ...BACBAC.... Naturally, these differences result in different numbers of Si (or C) resonances in the NMR spectrum (**Figure 3**). It becomes easy to distinguish (at least to some extent) the various polytypes (and their mixtures) by NMR.

An example of a sort of one-dimensional polytypism in the organic area is sulfathiazole (3). **Figure 4** shows the ^{13}C spectra of modifications III, IV, and V of sulfathiazole. It is immediately apparent that the spectrum of form III is very close in appearance to that of an overlap of the spectra of forms IV and V. The crystal structures must be closely related. Diffraction studies confirm this point: the

Figure 2 Nitrogen-15 CPMAS spectrum at 40.5 MHz of phenobarbital at natural isotopic abundance. Top: polymorph I; middle: polymorph II; and bottom: polymorph III.

Figure 3 Silicon-29 NMR spectra, obtained at 59.6 MHz, of silicon carbide polytypes: (a) 6H, (b) 4H, (c) 2H, and (d) 3C. Reproduced from *Journal of American Ceramic Society* 1991, 74: 777, with permission.

structure of each of the polymorphs is based on a common dimer, involving $\text{NH}\cdots\text{NH}_2$ and $\text{HN}\cdots\text{OS}$ hydrogen bonds. These dimers are linked into chains, which are again of the same type in all three forms. The chains are further joined into two-dimensional sheets by hydrogen bonds. In form V, these H-bonds are $\text{HNH}\cdots\text{N}$, whereas for form IV they are $\text{HNH}\cdots\text{OS}$. However, form III contains the two types in alternation, thus giving two molecules in the crystallographic asymmetric unit. This results in environments similar to those in both forms IV and V, thus explaining the relationship between the NMR spectra of the three forms.

Intermolecular and Intramolecular Interactions

As mentioned earlier, the differences between spectra of polymorphs are determined either by packing considerations (intermolecular) or by conformational variations (intramolecular) or both. Frequently, a prime cause of intermolecular differences lies in variations of hydrogen bonding. Thus, NMR spectra can be used to determine the nature of such bonding. For example, cortisone acetate (4) exists in at least three polymorphic forms (as well as numerous solvates). The structures of forms I and II are known, but not that of form III. The numbers of peaks in the ^{13}C CPMAS spectra show that forms I and II have a crystallographic asymmetric unit consisting of one

Table 1 Carbon-13 chemical shifts (in ppm) for three polymorphs of cortisone acetate (**4**)

Carbon	Form I	Form II	Form III
C-11	210.8	209.7	210.2s 209.7d
C-20	204.9	206.2	205.9s 203.7d
C-3	202.8	198.9	203.0d 198.2s
C-22	169.8	175.2	174.3s 171.5s 170.3s

d, double intensity; s, single intensity.

molecule (in accordance with the diffraction results), whereas there are three molecules in the asymmetric unit of form III. The chemical shifts for the carbonyl and ester carbons of these forms are given in **Table 1**. Hydrogen bonding is well known to shift the resonances to high frequency, and for cortisone acetate always involves the hydroxyl group at C-17 as the donor site. A comparison of the shifts shows that form I is hydrogen bonded at C-3, whereas the hydrogen bond for form II is at C-22, both in accord with the crystal structures. Interestingly, the NMR shows that two of the independent molecules of form III are hydrogen bonded at C-3, whereas the third has a hydrogen bond at C-22. None of the forms have hydrogen bonds through C-11 or C-20. Such information is obviously significant for any attempt to solve the crystal structure of form III. It should be noted that measurement of the chemical shift anisotropies provided the key to assigning the high-frequency signals for these polymorphs – in particular to distinguish the signal for the conjugated C-5 from those of the carbonyl and ester carbons.

Pi-stacking can also give characteristic intermolecular chemical shifts, thus distinguishing polymorphs.

The principal variations in chemical shifts between polymorphs arising from intramolecular effects are caused by changes in conformation. For example, the two polymorphs of oxybuprocaine hydrochloride (**5**) differ in the conformations of the *N*-diethyl side chains, resulting in the chemical shifts shown in **Table 2**. Form II contains

Table 2 Carbon-13 chemical shifts (in ppm) for the ethyl carbons of the diethylamino groups in oxybuprocaine hydrochloride (**5**)

Carbon type	Form I	Form II	Ethyl group ^a
CH ₂		52.6	A1
	50.8	50.0	B2
	49.9	49.3 40.5	A2 B1
CH ₃		11.2	A2
	10.6	10.3	A1
	9.4	10.1 4.6	B2 B1

^aThe independent molecules of form II are labeled A and B, with the two ethyl groups on each numbered 1 and 2.

two molecules in the asymmetric unit (and thus four relevant ethyl groups), whereas form I has only a single independent molecule. An INADEQUATE spectrum linked the corresponding CH₂ and CH₃ resonances. One CH₂ signal and one CH₃ signal of the same ethyl group for form II are at remarkably low frequencies. This indicates that an unusual conformation exists for this ethyl group and suggests a *gauche-gauche* arrangement for the methyl group with respect to the two other CH₂ carbons attached to the nitrogen (leading to the well-known γ -*gauche* shielding effect). Shielding computations suggest the assignments of all the signals to the individual carbons of the crystal structures (the spread in chemical shifts being largely due to the varying dihedral angles, some of which are far from the normal 60°, 120°, and 180° values). The INADEQUATE experiment tends to confirm all the links between the CH₂ and CH₃ resonances, though some ambiguities remain. The molecular conformation for form I is similar to that of molecule A of form II, as is reflected in the chemical shifts.

Mixtures and Quantification

NMR is readily capable of determining the proportions of different polymorphs in mixtures of forms, an ability that is highly useful for pharmaceutical systems. **Figure 5** shows partial ¹³C spectra of two forms of a pharmaceutical compound (not named here) and of a mixture of the forms. Strictly speaking, these are not polymorphs, since one of

Figure 5 Carbon-13 CPMAS spectra of two forms of a pharmaceutical drug molecule to illustrate the quantitative determination of mixtures. The amorphous form I is detected to be at the 10% level in crystalline form II.

them is probably amorphous. However, the principle of quantitative analysis for a mixture of forms by solid-state NMR is well illustrated by this case. It is clearly feasible to determine the presence of form II in form I down to 10% or less. Actually, this is the more difficult way round – it would be easier to determine the proportion of a crystalline form in a sample that is largely amorphous because this takes advantage of the smaller linewidth (and thus intrinsically higher peak heights) of crystalline forms.

Of course, a prerequisite for such determinations is the existence of at least one resonance comprising well-resolved signals for the two forms concerned. Also, due consideration must be given to any differences in relaxation times between the different forms. The problems that these can lead to are well illustrated by the polymorphs of sulfanilamide (6). The proton spin-lattice relaxation time of the β form is over an order of magnitude shorter than that for the α form at ambient temperature, thus creating potential errors in quantifying mixtures of the two forms. Such a difference is the result of differing rates of molecular-level mobility and is very temperature dependent. A substantial fraction of the α form in the β form can go undetected if recycle delays are short.

Solid-state NMR can be used to ascertain whether a sample of a compound is a pure polymorph or not. This may require it to be shown that all the peaks in the

Figure 6 Two-dimensional POST-C7 MAS ^{31}P spectrum of a mixture of two forms of $\text{Mg}_2\text{P}_2\text{O}_7$. The linked peaks belong to the α form. The mixing time was 600 μs .

Figure 7 Carbon-13 CPMAS spectrum at 75.4 MHz of a sample of polyethene containing three different types of domain.

spectrum are linked by coupling (dipolar or indirect). **Figure 6** shows as an example the ^{31}P spectrum of a mixture of forms of magnesium diphosphate, MgP_2O_7 . The one-dimensional spectrum consists of three peaks. The POST-C7 two-dimensional spectrum indicates that only two of them are coupled – these belong to the α form. It can be deduced that the third peak, which is not coupled to the others, belongs to a different form (the β form).

Many polymers are obtained in semicrystalline form and some have polymorphic crystallite structures. NMR provides a simple way of understanding the overall contents of such physically heterogeneous systems. **Figure 7** shows the ^{13}C CPMAS spectrum of a sample of high-density polyethene. Separate signals from the monoclinic,

orthorhombic, and amorphous forms can be clearly seen. The relative intensities can be quantified (with difficulty, because of the different relaxation properties of the three forms – the CP process results in partial suppression of the amorphous component). Other methods would struggle to obtain the fractional concentration of the two crystalline components in the total sample.

Phase Transitions

Phase transitions can be monitored and polymorphs unstable (or metastable) at ambient temperature can be studied by variable-temperature NMR. **Figure 8** shows ^{13}C spectra for the stable form II of hydroxytetracain hydrochloride (**7**) (also known as salicain) at ambient temperature and then after heating in the probe to a nominal 130°C .

Heating has clearly caused a transformation into a different polymorph, presumably form I, which is shown by the spectrum to have two molecules in the asymmetric unit (whereas form II has only one). The transition is said to occur at 140°C . The real temperature for the upper spectrum of **Figure 8** is likely to be in that region because of the heating caused by spinning at 10 kHz. In this case, form I can be studied at room temperature, after rapid cooling, though this is not easy because this form is readily hydrated (an isomorphic change).

Figure 9 shows ^{13}C CPMAS NMR spectra for a very different case, that of [*S,S*]-ethambutol hydrochloride (**8**), which undergoes single-crystal to single-crystal transformation between two enantiotropic forms at approximately 74°C . The phase change from form II to form I occurs very rapidly, taking no more than 10 s to complete, so monitoring its rate near the transition temperature is not feasible. In fact, what **Figure 9** shows is that there is a temperature gradient across the sample (in this case introduced deliberately). It would be possible to monitor the temperature variation within the sample by integrating the signals from the two forms!

Figure 8 Carbon-13 CPMAS NMR spectrum of hydroxytetracain hydrochloride (**7**) at 75.4 MHz. Top: form I at 130°C and bottom: form II at ambient probe temperature.

Figure 9 The ^{13}C CPMAS NMR spectra of [S,S]-ethambutol hydrochloride (**8**) at 50.33 MHz, taken in the vicinity of the transition temperature, 74°C , with a deliberate temperature gradient to show the transformation between form I (atoms indicated by X', where X is the atom number according to the structure of compound (**8**)) and form II (indicated by X). The average temperature for the upper spectrum is slightly higher than that for the lower spectrum. Reproduced from *Crystal Growth & Design* 2004, 4: 431, with permission.

Tin hexathiohypophosphate, $\text{Sn}_2\text{P}_2\text{O}_6$, can exist in at least two different phases. There is a second-order transition from the ambient-temperature ferroelectric phase to a paraelectric phase at approximately 70°C . **Figure 10** shows ^{119}Sn MAS spectra of the two phases. It is evident that there are two different environments for tin (and also for phosphorus) at ambient temperature, but only one at high temperature. This is consistent with the crystal structures. Although both phases are monoclinic, the high-temperature phase has the higher symmetry ($P2_1/n$ vs Pn).

Many second-order transitions between enantiotropic forms involve order–disorder phenomena. This sometimes requires the concept of a superlattice for the low-temperature form, which has a unit cell a number of times larger than that of the high-temperature form. This occurs, for example, for zirconium phosphate, ZrP_2O_7 , which has a relatively simple high-temperature cubic structure. The low-temperature form is also cubic but has a unit cell with each side three times the length for the high-temperature phase, that is, the form has a $3 \times 3 \times 3$ superlattice. The close relationship between the two structures means that the differences in the powder XRD patterns only involve low-intensity peaks, making structural determination of the low-temperature phase problematic. NMR was of key importance in the solution of the superlattice structure. The ^{31}P spectrum was shown, by two-dimensional methods (**Figure 11**), to have

Figure 10 Tin-119 spectra of polymorphs of $\text{Sn}_2\text{P}_2\text{S}_6$, obtained at 111.86 MHz. (a) Ferroelectric phase at ambient temperature and (b) paraelectric phase at 80°C (nominal). Reproduced from *Chemistry of Materials* 1993, 5: 1772, with permission.

an asymmetric unit with 13 $\text{P}_2\text{O}_7^{4-}$ units containing inequivalent phosphorus atoms and one symmetrical $\text{P}_2\text{O}_7^{4-}$ unit. This is only consistent with a *Pbca* space group (one of several possible in principle), and this conclusion enabled the powder XRD pattern to be solved to obtain the structure. A key part of this determination of the space group was the realization that the sample was pure (contrary to earlier suggestions) and that, therefore, all the peaks had to be taken into consideration. The proof of this fact was provided by a two-dimensional exchange spectrum, with a long mixing time, which showed cross peaks between all resonances. The difference between the polymorphs arises from the nature of the oxygen bridges linking the phosphorus atoms. These

Figure 11 Two-dimensional DQ/SQ dipolar MAS ^{31}P spectrum of ZrP_2O_7 , obtained using the POST-C7 pulse sequence. MAS rate 10 kHz. The vertical scale indicates the double-quantum dimension. Horizontal lines link signals for P_2O_7 pairs of phosphorus nuclei. The lowest linked signals are triply degenerate. The top right-hand signal is a genuine autocorrelation peak, and the arrow indicates an artifact (as shown by further experiments).

bridges are mostly nonlinear in the low-temperature form and are fixed in position, being in different positions in the small cubes forming the superlattice. Rotation of the oxygen atoms about the $\text{P}\cdots\text{P}$ directions renders the $\text{P}_2\text{O}_7^{4-}$ groups equivalent in the high-temperature form.

Disorder and Dynamics

NMR is of particular value when there is disorder in a crystalline compound. A remarkable example of this is provided by the dyestuff Disperse Red 278 (DR278) (9), which has (at least) three polymorphs. Forms A and B have disorder apparently connected with the conformation of the more heavily substituted aromatic ring about the azo-ring bond, whereas form C has a fixed single conformation. The NMR spectra (Figure 12) clearly show the different numbers of signals found for these two situations. Although the existence of disorder can be

Figure 12 Carbon-13 CPMAS spectrum of three polymorphs of the dyestuff DR278 (9). (a) Form A, (b) form B, (c) form C, and (d) the melt at 150 °C. Two different conformations are present in forms A and B but only one in form C. Reproduced from *Journal of the Chemical Society, Perkin Transactions* 1996, 2: 1733, with permission.

detected by diffraction methods, only NMR could show (for form A) that this is a case of dynamic disorder rather than of a fixed spatial distribution. Variable-temperature NMR measurements enabled the determination of the energy barrier to the exchange process involved. This is likely to consist mainly of pseudorotation of the azo group, with little movement of the other atoms, thus giving a relatively low barrier to the process. It is noteworthy, especially for form C (which contains 12 well-resolved aromatic signals), that internal rotation of the phenylene group is slow on the NMR timescale at ambient probe temperature, whereas in the melt (Figure 12(d)) there are only 10 such peaks, indicating rapid internal rotation.

The ability of NMR to detect and measure mobility in solid polymorphs (to different extents in different forms of the same compound) is exemplified by formoterol fumarate (10). This also contains a phenylene group, which, as in many solids, can rotate at a rate commensurate with the NMR timescale. On heating various forms of this compound, the four lines for the phenylene CH carbons merge into two as the lifetimes for the separate conformations increase as internal rotation becomes more rapid.

Conclusion

The above discussion shows how valuable solid-state NMR is for identifying and characterizing the various polymorphic forms of a wide range of chemical compounds. Information is gained on both structure- and molecular-level dynamics. The topic forms part of the subject of NMR crystallography and the techniques are best used together

with (being complementary to) the well-established diffraction protocols for determining crystal structure. Some matters relating to NMR studies of polymorphism, such as computation of chemical shifts, have not been discussed herein (but see the section Further Reading).

Functional methods are gaining increasing interest in medicine for both improved diagnostics and therapy management. Positron emission tomography (PET) had been used for more than 20 years, but was mainly confined to research centers due to the technological demands. The availability of block detector systems has promoted the use of PET, primarily in oncology due to the possibility to examine larger areas of the body, even to do whole body scans. The development of combined PET/CT systems was another major step forward to improve the information for oncological diagnostics and therapy planning. Thus, morphological and functional information can be acquired and assessed from the same target volumes nearly at the same time. Recently, some work had been initiated even to combine PET with magnetic resonance imaging (MRI).

In contrast to conventional nuclear medicine procedures, PET is based on radiopharmaceuticals labeled with positron emitters. Owing to the properties of these isotopes, namely, the high energy of 511 keV, plus a decay resulting in the emission of two gamma rays at an angle of 180°, the resolution of PET systems is usually within 2.2–5 mm, which is by far superior to conventional nuclear medicine imaging methods. The state-of-the-art systems include sophisticated methods to identify the photopeaks within the detector crystals more accurately and achieve a spatial resolution of 2–3 mm for the whole target area. Another aspect is 3D data acquisition, which increases the number of counts significantly as compared to the 2D mode, as well as the use of alternative detector

materials like lutetium oxyorthosilicate (LSO) instead of bismuth germanate (BGO), which improves the counts statistics.

Nuclear medicine procedures are generally based on the use of radiopharmaceuticals. Although the isotope is needed to provide a signal that can be measured by an appropriate device, the pharmaceutical determines the specificity of the information that is measured. The use of different radiopharmaceuticals is helpful in obtaining different functional information. The most commonly used radiopharmaceutical for PET examinations is ¹⁸F-labeled deoxyglucose (FDG). FDG is a substrate for the glucose transporters and is transported like glucose into the cells and phosphorylated, but then mainly trapped in the cells. Therefore, images approximately 1 h after FDG injection provide information primarily about the metabolized fraction of FDG in the tissue. As an alternative to static images 1 h after tracer injection, a dynamic acquisition for 1 h can be done, followed by additional static images and repositioning of the patient to obtain partial or whole body images. The dynamic data set can be used to retrieve detailed information from the time–activity data using compartment modeling, and this information can be helpful, for example, in identifying early changes in FDG metabolism following treatment.

Neurology

PET enables the examination of brain functions. Brain studies are performed with FDG to assess the glucose metabolism. A reduction in FDG uptake in brain is frequently associated with a brain dysfunction, like epilepsy or Alzheimer's disease. An increased accumulation of FDG can be noted, for example, in acute epilepsy. Perfusion studies with ¹⁵O-water are used for the study of brain perfusion. For the diagnosis of movement disorders, as in Parkinson's disease, dedicated radiopharmaceuticals, such as ¹⁸F-dihydroxyphenylalanine (¹⁸F-DOPA) have been developed. ¹⁸F-DOPA is taken up by the dopaminergic neurons and provides information about the function of presynaptic dopaminergic receptors. For the detection of an epileptogenic focus, ¹¹C-raclopride (a D2-receptor ligand) is used. ¹¹C-flumazenil (FMZ) is frequently applied for the detection of an epileptogenic focus. FMZ binds to γ-aminobutyric acid (GABA), the principal inhibitory neurotransmitter in brain, which is reduced in epilepsy.

Cardiology

PET with FDG is used for cardiac studies primarily to detect the viability of the myocardium, to identify ischemic disease, and to evaluate the extent of disease in patients being considered for interventional revascularization or transplantation procedures. Other radiopharmaceuticals, like ^{15}O -water or ^{13}N -ammonia, can be used for cardiac perfusion studies. Tracers for hypoxia imaging are in development. Another approach consists of apoptosis measurements with ^{124}I -annexin V, a procedure that is currently under evaluation. Annexin is a phospholipid binding protein with high affinity for phosphatidyl-serine, which is externalized by cells undergoing programmed cell death. ^{124}I -annexin is accumulated in the infarct site indicating that cardiomyocytes with externalized phosphatidyl-serine are present in the infarct area. Therefore, an accumulation of this tracer gives evidence for apoptotic processes.

Oncology

The majority of routine PET examinations are performed for oncological reasons. For oncological studies, the radiopharmaceutical FDG is primarily used. FDG is taken up by malignant tumors in a higher amount as compared to normal tissue and can therefore be used for diagnosis, staging, and monitoring of treatments effects following chemotherapy and radiation therapy. In particular, the diagnosis of a tumor recurrence is a domain for PET with

Figure 1 FDG PET/CT image of a malignant tumor in the central part of the left lung. The CT image demonstrates a left central mass, extending to the thoracic wall. The parametric image of the FDG metabolism shows clearly the active part of the tumor in the central part of the mass identified in CT. Therefore, the peripheral part of the mass is not a malignant lesion but an atelectasis (collapsed lung tissue) caused by occlusion of the lung by the centrally located tumor.

FDG. Aggressive tumors accumulate FDG and can be visualized without problems in most cases (**Figure 1**). Problems may arise in slowly growing tumors (so-called grade I), such as some soft tissue sarcomas, prostate carcinomas, well-differentiated hepatocellular carcinomas, or neuroendocrine tumors, which may not accumulate glucose sufficiently to be detected with FDG and PET.

Other radiopharmaceuticals, like ^{15}O -water, are used in clinical studies for the measurement of the tumor perfusion or to assess the access to a tumor using a systemic and an intraarterial application of the radiopharmaceutical.

Labeled cytostatic agents, like ^{18}F -fluorouracil, ^{13}N -cisplatin, ^{18}F -paclitaxel, and others, are used in experimental studies to examine the pharmacokinetics of the drugs *in vivo*.

Labeled amino acids, like ^{11}C -methionine, which reflect the amino acid transport, are in use for the visualization of brain tumors, in particular for high-grade gliomas. ^{11}C -thymidine and a derivative, F-18-fluoro-3'-deoxy-3'-L-fluorothymidine (FLT), are used to assess the proliferation of a malignant mass.

One area of particular interest is related to receptor binding tracers, because they provide specific information about lesions. Labeled peptides, like ^{68}Ga labeled 1,4,7,10-tetraazacyclododecane-N, N', N'', N'''-tetraacetic-acid-D-phe-Tyr3-octreotide (DOTATOC), a substrate for the somatostatin receptor II (SSTR2), are used in neuroendocrine tumors for tumor visualization and therapy planning. Labeled with ^{90}Y , a β -emitting isotope, DOTATOC can be used for treatment of SSTR2 expressing tumors. ^{68}Ga -bombesin, another receptor avid tracer, binds to three receptors: gastrin-releasing peptide receptor (GRPR), neuromedin B, and the bombesin receptor subtype 3. The tracer is currently in evaluation for different tumor histologies, including brain tumors, gastrointestinal stromal tumors, and colorectal carcinomas.

Diagnostic Aspects

One primary problem in patients with malignant lesions is the accurate initial staging. Although morphological methods like computed tomography (CT) and MRI are commonly used to identify and delineate masses and to achieve a classification according to the morphological information provided by these methods, PET can help to improve the staging accuracy by adding functional information and thus improve the overall accuracy of the staging procedure. The use of PET in patients with brain tumors was one of the first applications of this method. FDG can help to differentiate low-grade from high-grade brain tumors. The sensitivity and specificity were 94 and 77% when a tumor-to-white matter ratio of 1.5 was chosen. Owing to the low FDG accumulation in low-grade lesions, multitracer PET studies with radiolabeled amino acids like ^{11}C -methionine or ^{11}C -tyrosine can be useful, for example,

for the improved detectability of low-grade brain tumors. Although the uptake of FDG is moderate in the normal brain, amino acids usually exhibit a low transport into normal structures. Therefore, the lesion-to-normal ratio is generally higher as compared to FDG. Another approach is the use of receptor-specific agents like ^{68}Ga -DOTATOC. Furthermore, initial studies with the receptor-specific tracer ^{68}Ga -bombesin are promising and have shown an enhanced binding in gliomas, most likely due to an enhanced expression of neuromedin B. ^{68}Ga -bombesin seems to be helpful in the delineation of the tumor areas with a high receptor density.

For several years now, PET has found increasing interest for studies of malignancies in the whole body area, primarily with the use of FDG. It is known from the literature that morphological methods like CT and MRI are helpful in assessing anatomical details and detecting abnormalities. However, the accuracy is different according to tumor histology. The additional use of a functional method like PET can enhance the accuracy to detect and delineate a tumor. A meta-analysis of the literature regarding the staging accuracy of lung tumors revealed an average sensitivity and specificity of 57 and 85%, respectively, for CT, whereas PET with FDG achieved sensitivity and specificity of 83 and 92%, respectively. Another problem in lung tumors is the early detection of tumor recurrence, which is important to initiate an appropriate treatment. Based on a literature review, the average sensitivity and specificity of PET was 98 and 92%, respectively, whereas CT had a sensitivity and specificity of 72 and 95%, respectively. One important aspect is the combination of morphological and functional methods, either by PET/CT systems or by soft fusion of PET and morphological imaging modalities. Strauss and Dimitrakopoulou-Strauss evaluated the tumor staging with CT alone as well as with PET/CT system in patients with malignant lung tumors and compared the tumor classification (T-staging) with the surgical results. In 40% of the patients, a correct change in the T-staging was initiated based on the PET results. Other authors report comparable results with a change in the tumor stage in up to 41% of the patients.

In most cases, a whole body data acquisition is the standard procedure to visualize tumorous lesions in the whole body area using FDG and PET, which is helpful especially in the assessment of less locally confined diseases, for example, for the initial staging of malignant lymphomas, malignant melanomas, and small-cell lung cancer. The sensitivity and specificity in malignant lymphomas exceeds 85% in the majority of the studies reported in the literature. Comparable data are reported for malignant melanomas, colorectal carcinomas, head and neck tumors, sarcomas, breast carcinomas, and pancreatic carcinomas. A modified whole body acquisition protocol is used routinely at the German Cancer

Research Center. Initially, a dynamic PET study for 60 min is performed over the primary target area, mainly the position of the primary or recurrent tumor. Then additional static acquisitions are performed with repositioning of the patient to acquire a whole or partial body scan. Thus, the tracer kinetics in the tumor can be quantitatively assessed using more sophisticated methods like compartment and noncompartment modeling, and detailed information is obtained about the biological properties of a lesion.

The sensitivity and specificity of FDG PET depends among other parameters on the lesion location, size, and the contrast of a mass in relation to the tracer uptake in the surrounding tissue. Therefore, PET with FDG is of limited value for the differentiation of space occupying masses of the kidney due to the high tracer accumulation in the normal renal parenchyma. The differentiation of small ovarian tumors can be difficult due to the FDG uptake in normal structures within the target area. Increased tracer uptake in normal structures may raise problems also in the diagnosis of prostatic cancer. The differentiation of small lesions, for example, involved, but normal-sized lymph node metastases, located in metabolically active tissue, can also raise problems. Submandibular lymph node metastases of head and neck tumors cannot always be delineated due to the normal FDG uptake in the glands. Furthermore, the uptake of FDG is also dependent on the histology of a tumor. Highly differentiated hepatocellular carcinomas are difficult to be delineated from the normal liver parenchyma due to a nearly liver equivalent FDG uptake. In contrast, according to our data in lymphoma patients, the diagnosis of normal-sized mediastinal lymph node metastases is usually not a major problem, since 90% of the involved lesions demonstrated a higher FDG uptake than the blood background activity.

Another limiting parameter for FDG PET studies is the differentiation between inflammation and viable tumor tissue. It is known that acute inflammatory processes frequently have a high FDG uptake and may not be differentiated from viable tumor tissue. Experimental studies with FDG and ^3H -deoxyglucose in tumor-bearing mice using a microautoradiographic technique demonstrated that 29% of the measured FDG uptake in a tumor lesion is due to inflammatory or other benign elements like granulation tissue and macrophages. The use of a second PET tracer may be helpful in these cases to gain additional information. According to our preliminary data using multitracer PET studies in patients with inflammatory masses, liver tumors, colorectal tumors, soft tissue sarcomas, and recurrent lymphomas, a specific marker of the A-type amino acid transport, ^{11}C -aminoisobutyric acid (^{11}C -AIB), did not show any significant accumulation in inflammatory lesions. Therefore, a combination of ^{11}C -AIB with FDG may be helpful in

differentiating inflammation from viable tumor tissue. However, more data are needed to evaluate the multi-tracer PET approach for clinical purpose.

Therapy Management

In patients scheduled for further treatment due to a tumor, problems may arise due to the differentiation of benign structures from residual or recurrent tumor tissue. PET can be helpful by improving the diagnostic accuracy based on the use of metabolically active tracers. Recurrent brain tumors sometimes may provide diagnostic problems if FDG is used for PET due to the enhanced tracer uptake in the normal brain. The use of other tracers like O-(2-[^{18}F]Fluoroethyl)-L-tyrosine (FET) or FLT is usually more helpful than FDG in delineating a recurrent tumor tissue in brain (**Figure 2**).

Some of the most common tumors in the whole body area are colorectal carcinomas. Follow-up studies have shown that the early detection of tumor recurrence is important for the treatment of these patients. The use of a metabolically active tracer like FDG has found use for

Figure 2 Recurrent oligodendroglioma of the brain. Upper: FDG image demonstrating a low FDG accumulation in the area of the recurrent tumor. Lower: Image obtained 1 h after the intravenous injection of FLT. The tracer is a substrate for the thymidine kinase 1 and is associated with cell proliferation. The tracer shows a moderate accumulation in the recurrent tumor, giving evidence for a low proliferation rate of the lesion.

the differentiation of recurrent tumor and scar, because malignant masses usually take up more FDG than benign lesions, except inflammatory areas. Most of the studies reported in the literature reveal a sensitivity of PET that exceeds 90%. Besides the detection of a recurrent tumor, metastatic lesions can be identified if partial or whole body data acquisitions are performed with PET. Comparable results are also reported for other tumor histologies.

Usually, changes in metabolism precede changes in tumor volume. Therefore, follow-up measurements of the tumor metabolism can be used to assess therapeutic effects earlier and more accurately than based on morphological changes. Even the simple, visual assessment of FDG PET images before and following treatment may be helpful in gaining information about the effect of a treatment protocol. For example, this had been shown in patients with lymphomas.

A quantitative approach provides more accurate information about the tracer kinetics than the visual assessment of images. The authors have introduced the term 'standardized uptake value' (SUV) for the following tracer concentration ratio: $\text{SUV} = \text{concentration in the target volume (Bq g}^{-1}) / (\text{injected dose (Bq)} / \text{body weight (g)})$. Thus, the tracer concentration in a target area is normalized for the injected dose and the distribution volume, which is approximated by the body weight. The ratio has no dimension and reflects the relative distribution of the tracer. $\text{SUV} = 1$ is achieved, if the tracer distributes freely in the whole volume, because in this case the target concentration always matches the mean concentration (denominator in the SUV equation). The calculation of the SUV for malignant lesions is a standard procedure at many PET centers now. The change in FDG SUV before and after chemotherapeutic treatment is frequently used to assess the response to therapy. Several studies have been performed in breast carcinomas, lymphomas, head and neck tumors, melanomas, and lung tumors, demonstrating that the change in FDG SUV before, during, and after treatment reflects the response to treatment.

At present, there are no generally accepted criteria for the definition of response. Generally, a reduction in the FDG uptake is a good prognostic sign. A threshold of at least 20% had been proposed by some authors as a response criterion. However, even a 20% change does not necessarily correlate to the individual survival rate, but is associated with at least a palliative effect. In contrast, an increase in the FDG uptake is usually associated with nonresponse. The thresholds depend on the tumor type and the expected curative or palliative treatment effect. In patients with malignant lymphomas, who primarily respond to chemotherapy, a decrease of 45% had been reported even within 24 h after onset of therapy. The threshold for metabolic response in high-grade lymphomas

is therefore higher, because the primary intention is to cure the tumor. In case of palliative chemotherapy, the threshold may be significantly lower. Thus, using metabolic measurements seems to be feasible to individualize and optimize chemotherapy.

The quantification of the tracer uptake by calculating the SUV is helpful; however, to achieve detailed information about the tracer kinetics, compartment modeling is needed. In particular, for monitoring palliative chemotherapeutic protocols, which often lead to only small metabolic changes, a detailed analysis of the kinetic tracer data may be used and is superior to the use of just one uptake value. For FDG usually a two-tissue-compartment model is applied. This model is based on five parameters: the transport of the tracer into and out of the cells (k_1 , k_2), the phosphorylation and dephosphorylation of the intracellular FDG (k_3 , k_4), and the distribution volume of the tracer (VB), also associated with the vessel density in a target volume. Most programs use an iterative approach to solve the differential equations of this model. The kinetic parameters provide detailed information about the change in FDG tracer concentrations. This can be helpful in assessing specific treatment protocols. For example, it is known from experimental studies that the glucose transporters expression is closely associated with angiogenesis-related gene expression, especially the vascular endothelial growth factor A (VEGF-A). Therefore, k_1 , which reflects the transport of FDG into the tissue, is an indirect measure of the angiogenesis in a tumor. These data can be helpful, for example, if antiangiogenetic treatment is considered in a patient. Although most of the therapy-related studies are based on the calculation of the SUV, only a few studies

are published using full kinetic data. For the kinetic data analysis, a dynamic PET data acquisition must be performed, which is more time-consuming as compared to the standard whole body technique. Some studies have been published using dynamic PET data, primarily in metastatic colorectal tumors and lung tumors. The results demonstrate that the kinetic data can be used even to predict individual survival following chemotherapeutic treatment.

The analysis of tracer kinetics is primarily done using a volume-of-interest (VOI) to retrieve the tracer concentrations. Thus, the kinetic analysis provides data about a dedicated target volume. If the analysis is expanded and applied to each voxel, parametric images can be calculated to visualize the kinetic information as images. Owing to the computational demands of the two-tissue-compartment model algorithm, more simple approaches are frequently used to achieve the information about the metabolism of a tracer. Fast models with limited computational demands involve the calculation of the metabolic rate based on the Patlak algorithm or the calculation of regression images, reflecting the retention of the tracer. Recently, a new approach based on a combination of a database and discriminant analysis algorithm had been developed, which can be used to calculate images even of the two-tissue-compartment model on a voxel base within moderate calculation times.

Perfusion studies with ^{15}O -water can be used in combination with FDG studies to monitor the effect of a neoadjuvant therapy. In patients with locally advanced breast carcinoma who received neoadjuvant chemotherapy, an increase in tumor perfusion was noted in nonresponders by a concurrent decrease in the metabolic

Figure 3 Recurrent meningioma following surgery. Radiation treatment is planned. Based on the MRI image (left), the whole area of the mass would be treated, which involves both optical nerves, resulting in loss of vision. The fusion of the MRI image with a parametric image of the receptor density using ^{68}Ga -DOTATOC PET reflects the SSTR2 expression in the recurrent tumor. Interestingly, a small part of the mass in the area of the right optical nerve is not tumor but scar tissue (right image, area within the white circle). Based on the PET results, radiation treatment can be confined to the tumor itself and the right optical nerve will be saved.

rate of FDG. Furthermore, patients with breast carcinoma whose tumors demonstrated a higher ratio for the metabolic rate of FDG and tumor perfusion survived longer. Perfusion studies with ^{15}O -water PET can also be used to monitor the effect of an antiangiogenic therapy. This is a difficult task because inhibitors of angiogenesis are not primarily cytotoxic and therefore it takes a longer time to assess the biological effect. In oncological patients treated in a phase I study (dose finding study) with a human recombinant endostatin analogue, which has an antiangiogenic effect, PET studies with ^{15}O -water demonstrated a change in the tumor perfusion, which was associated with the dose escalation of the drug. Specific information can also be obtained by ^{68}Ga -DOTATOC, which binds to the SSTR2 receptor. This receptor is enhanced, for example, in neuroendocrine tumors and meningiomas. Therefore, ^{68}Ga -DOTATOC has found use for the improved delineation of recurrent meningiomas before radiation treatment (**Figure 3**). Studies with ^{68}Ga -DOTATOC have found use also to plan and assess the effect of a radioisotope therapy with ^{90}Y -DOTATOC, which is an experimental therapy used for

the treatment of metastatic neuroendocrine tumors. Only neuroendocrine tumors, which show an enhanced uptake on ^{68}Ga -DOTATOC PET are candidates for the radioisotope therapy.

Symbols

A_m, B_n	Fourier coefficients
A^D	distortion coefficient
A^S	size coefficient
B	isotropic atomic displacement
d	interlayer spacing
D	crystallite diameter
e	microstrain
f	atomic scattering factor
F	structure factor
h, k, l	Miller indices
I	intensity
L_p	angle-dependent factor
m	Pearson exponent
M_{20}	de Wolff figure of merit
m_k	reflection multiplicity
N	site occupation factor
R	goniometer circle radius
R_p	profile factor
s	scale factor
W	weight fraction
Z	number of molecules per unit cell
β	integral breadth
δ	specimen displacement
ε	apparent crystallite size
η	pseudo-Voigt mixing factor
θ	diffraction angle
λ	wavelength
ϕ	shape factor
Φ	line-profile function

Introduction

X-ray powder diffraction is a nondestructive technique widely used for the characterization of micro-crystalline materials. The method has been traditionally applied for phase identification, quantitative analysis and the determination of structure imperfections. More recently, applications have been extended to new areas, such as the determination of moderately complex crystal structures and the extraction of three-dimensional microstructural properties. This is the consequence of the higher resolution of modern diffractometers, the advent of high-intensity X-ray sources and the development of line-profile modelling

approaches to overcome the line overlap problem arising from the one-dimensional data contained in a powder diffraction pattern. The method is normally applied to data collected at room temperature. Nevertheless, it is also used with data collected *in situ* as a function of an external constraint (temperature, pressure, electric field, atmosphere, etc.), offering a useful tool for the interpretation of chemical reaction mechanisms and materials behaviour. Various kinds of microcrystalline materials may be characterized from X-ray powder diffraction, such as inorganic, organic and pharmaceutical compounds, minerals, catalysts, metals and ceramics. For most applications, the amount of information which can be extracted depends on the nature and magnitude of the microstructural properties of the sample (crystallinity, structure imperfections, crystallite size), the complexity of the crystal structure and the quality of the experimental data (instrument performance, counting statistics).

Line Profile Parameters

The observed diffraction line profiles are distributions of intensities $I(2\theta)$ defined by several parameters. The most commonly used measure for the reflection angle is the *position* $2\theta_0$ of the maximum intensity (I_0). It is related to the lattice spacing d of the diffracting hkl plane and the wavelength λ by Bragg's law.

$$\lambda = 2d \sin \theta$$

The *dispersion* of the distribution, or diffraction line broadening, is measured by the full width at half the maximum intensity (FWHM) or by the integral breadth (β) defined as the integrated intensity (I) of the diffraction profile divided by the peak height ($\beta = I/I_0$). Line broadening arises from the convolution of the spectral distribution with the functions of instrumental aberrations and sample-dependent effects (crystallite size and structure imperfections). Since Fourier-series methods play an important role in X-ray diffraction by imperfect solids, the coefficients (A_m, B_n) of the Fourier series used to represent a line profile are also characteristics of the line broadening. The line *shape factor* is described by the ratio ϕ of the FWHM to the integral breadth ($\phi = \text{FWHM}/\beta$). There are alternative shape factors according to the analytical functions Φ , given in

Table 1 Some flexible line-profile functions $\Phi(x)$ used to model powder diffraction line profiles (L and G denote the Lorentzian and Gaussian functions, respectively)

Name	Function	Shape factor
Pseudo-Voigt (p-V)	$C_1[\eta L + (1 - \eta)G]$ (η, C_1 : adjustable parameters)	Mixing factor η $\eta=1$ Lorentzian shape $\eta=0$: Gaussian shape $\eta > 1$: super-Lorentzian shape
Pearson VII (PVII)	$C_2(1 + Cx^2)^{-m}$ (m, C, C_2 : adjustable parameters)	Exponent m $m=1$: Lorentzian shape $m=\infty$: Gaussian shape $m < 1$: super-Lorentzian shape
Voigt (V)	$C_3 \int L(x')G(x - x')dx'$ (C_3 : adjustable parameter)	$\phi = \text{FWHM}/\beta$ $\phi=0.6366$: Lorentzian shape $\phi=0.9394$: Gaussian shape

Table 1, commonly used for modelling individual diffraction lines, e.g. the mixing factor η for the pseudo-Voigt and the exponent m for the Pearson VII. The *area* is defined by the integrated intensity I of the diffraction line. It is related to the atomic content and arrangement in the unit cell, to the amount of diffracting sample and to angle-dependent factors (Lp). It is proportional to the square of the structure factor amplitude F_{hkl} :

$$F_{hkl} = \sum_j N_j f_j \exp 2\pi i(bx_j + ky_j + lz_j) \\ \times \exp(-B_j \sin^2 \theta / \lambda^2)$$

where N_j is the site occupation factor, f_j is the atomic scattering factor, B_j is the isotropic atomic displacement (thermal) parameter, b , k and l are the Miller indices, and x_j , y_j and z_j are the position coordinates of atom j in the unit cell. **Table 2** lists the specific applications of the powder diffraction method according to the line-profile parameters.

Table 2 Main applications of X-ray powder diffraction

Diffraction line parameter	Applications
Peak position	Unit-cell parameter refinement Pattern indexing Anisotropic thermal expansion Homogeneous stress Phase identification
Line intensity	Phase abundance Chemical reaction kinetics Crystal-structure determination and refinement (whole pattern) Search/match ($d - I$) Space-group determination ($2\theta_0$ -absent I_{hkl}) Preferred orientation
Line width and shape	Instrumental resolution function Microstructure
Line-profile broadening	Microstructure (crystallite size, size distribution, lattice distortion, structure mistakes, dislocations, composition gradient), crystallite growth kinetics

Diffraction Geometry and Data Collection

For most applications it is essential that the powder diffraction data be collected appropriately. Therefore, it is of prime importance to spend time optimizing the adjustment of the diffractometer, the quality of the radiation employed and the randomization of the crystallites in the sample. There are several designs for X-ray powder diffractometers (reflection or transmission modes), each of them having advantages and disadvantages. **Figure 1** shows an optics arrangements commonly used with conventional divergent-beam X-ray sources, based on the Bragg–Brentano para-focusing geometry. The beam converges on the receiving slit after diffraction by the sample. The geometry is characterized by two circles, the goniometer circle with a constant radius R and the focusing circle with a radius dependent on θ . It uses a

flat sample which lies tangentially to the focusing circle. The main advantage of this reflection geometry is that no absorption correction has to be made if an ‘infinitely’ thick sample is used. Disadvantages are that by using a flat sample, preferred orientation effects are increased and at low angles the illuminated area can become larger than the sample. Preferred orientation effects can be reduced by using side-loaded sample holders. The most frequent angular errors arise from a shift of the zero- 2θ position and a displacement δ of the specimen from the goniometer axis of rotation ($\Delta 2\theta = 2\delta \cos \theta / R$). Transmission geometry, often combined with a position-sensitive detector (PSD), can be employed with thin flat samples or capillaries. The main advantages are the small amount of sample used and, with capillaries, the reduction of preferred orientation. Transmission optics are ideal for ‘transparent’ materials, containing only light

Figure 1 Optics of a conventional focusing powder diffractometer with monochromatic X-rays (Bragg–Brentano geometry with a reflection specimen): F line focus of X-ray tube, M incident-beam monochromator, a short focal distance, b long focal distance, FS focal slit, S flat specimen, GC goniometer circle, O goniometer axis, R goniometer radius, FC focusing circle, θ Bragg angle, 2θ reflection angle, RS receiving slit, D detector.

Figure 2 The quartz cluster of reflections 212, 203 and 301 collected with $\text{CuK}\alpha_1$ radiation (continuous line) and with the $\text{CuK}\alpha_1$ – $\text{K}\alpha_2$ doublet (circles).

atoms, but for highly absorbing materials, patterns are difficult to measure. X-ray synchrotron radiation presents some important advantages over conventional X-ray sources. The excellent angular collimation combined with the wavelength tunability and high brightness of the synchrotron source make it ideal for many types of X-ray diffraction experiments. Moreover, with parallel-beam optics, sample-displacement aberrations in diffraction lines are completely eliminated.

Although a basic requirement of the Bragg law is the use of monochromatic radiation, the doublet $\text{K}\alpha_1$ – $\text{K}\alpha_2$ from copper is the most popular wavelength used with

laboratory diffractometers. However, for the more demanding applications it is desirable to remove the $\text{K}\alpha_2$ component with a monochromator located in the incident beam (**Figure 1**). There is some reduction in the intensity of $\text{K}\alpha_1$, but the number of reflections in the pattern is halved and thereby the degree of line overlap is reduced. **Figure 2** shows the improvement in resolution achieved with the monochromatic $\text{CuK}\alpha_1$ radiation ($\lambda = 1.5406 \text{ \AA}$) with respect to the $\text{K}\alpha_1$ – $\text{K}\alpha_2$ doublet.

The performances of powder diffractometers are determined by the precision of peak position measurements and the instrument resolution function (IRF), normally

expressed by the angular dependence of the FWHM obtained with a reference material. The most widely used standard reference materials (SRMs) for diffractometer characterization are those from the National Institute of Standards and Technology (NIST). For instance, powders of Si (SRM 640b, $a = 5.430940 \pm 0.000035$ Å) and fluorophlogopite mica (SRM 675, interlayer spacing $d_{001} = 9.98104 \pm 0.00007$ Å) are proposed as d -spacing standards, while LaB₆ (SRM 660) is recommended as a line-profile standard. With laboratory X-ray diffractometers errors on peak positions can be less than $0.01^\circ(2\theta)$ and the IRF has typically a minimum around $0.06^\circ(2\theta)$ at intermediate angles, increasing to twice this value at $\sim 130^\circ(2\theta)$ as a consequence of spectral dispersion. The best instrumental resolution (~ 0.01 – $0.02^\circ 2\theta$) is obtained with the synchrotron parallel beam optics with a crystal analyser mounted in the diffracted beam. This is of particular interest in some applications, such as the study of complex crystal structures.

Pattern Modelling

Pattern modelling techniques are used in most current applications. The intensity at point x_i in the calculated pattern is given by

$$J_{\text{cal}}(x_i) = \sum_k I_k \Phi(x_i - x_k) + b(x_i)$$

where I_k is the integrated intensity of reflection k , Φ is one of the normalized profile functions given in **Table 1** and $b(x_i)$ is the background contribution. The summation is over all reflections contributing to the intensity at point x_i . Parameters defining the model are refined until the quantity

$$S = \sum w(x_i) [J_{\text{obs}}(x_i) - J_{\text{cal}}(x_i)]^2$$

is a minimum, the summation being over all data points in the diffraction pattern with $w(x_i)$ being the appropriate weighting factor. Although a visual inspection of the difference curve between observed and calculated patterns is the best way to judge the quality of the fit over the whole angular range, numerical factors are used to assess the quality of the final refinement. These are listed in **Table 3**.

Pattern Decomposition

This is a systematic procedure for decomposing a powder pattern into its component Bragg reflections without reference to a structure model and, thereby, line-profile parameters ($2\theta_0$, I_0 , I , FWHM, β , shape factors) are extracted. **Figure 3** shows the fitting of pseudo-Voigt functions to the individual lines of the pattern of a ZnO sample displaying diffraction line broadening. However,

Table 3 Some numerical criteria of fit used in pattern-fitting methods

<i>R</i> -profile	$R_p = \frac{\sum y_i(\text{obs}) - y_i(\text{cal}) }{\sum y_i(\text{obs})}$
<i>R</i> -weighted profile	$R_{wp} = \left[\frac{\sum w_i [y_i(\text{obs}) - y_i(\text{cal})]^2}{\sum w_i [y_i(\text{obs})]^2} \right]^{1/2}$
<i>R</i> -structure factor	$R_F = \frac{\sum I_{hkl}(\text{'obs'})^{1/2} - I_{hkl}(\text{cal})^{1/2} }{\sum I_{hkl}(\text{'obs'})^{1/2}}$
<i>R</i> -Bragg factor	$R_B = \frac{\sum I_{hkl}(\text{'obs'}) - I_{hkl}(\text{cal}) }{\sum I_{hkl}(\text{'obs'})}$

for extracting integrated intensities over the complete pattern, for a subsequent structural analysis, an approach incorporating constrained peak positions, according to the refined unit-cell dimensions and to the space group, allows the generation of only space-group allowed intensities.

The Rietveld Method

In the Rietveld method an observed and a calculated powder diffraction pattern are compared and the difference is used to refine the atomic coordinates of the structure model. The calculated intensity at point x_i is given by the equation

$$J_{\text{cal}}(x_i) = s \sum_k m_k (Lp)_k |F_k|^2 P_k \Phi(x_i - x_k) + b(x_i)$$

where s is a scale factor, m_k is the reflection multiplicity and P_k is a function to deal with the preferred orientation of the crystallites. They are two groups of refined parameters arising from the structure model (atomic coordinates x_j , y_j and z_j , atomic displacement parameters, unit-cell dimensions) and the instrumental model (angular dependence of the profile parameters, FWHM and shape factors, 2θ -zero position, preferred orientation, etc.). Recommendations for Rietveld-refinement strategies have been formulated by the Commission on Powder Diffraction of the International Union of Crystallography. **Figure 4** shows a typical final Rietveld plot obtained from powder data collected with the capillary method. The precision of a structure refinement depends on many factors, e.g. the number of parameters to be refined, data quality (preferred orientation, counting statistics, anisotropic line broadening), the contrast between atoms and the size of the unit cell. Moreover, structure refinement from X-ray diffraction data is strongly influenced by the fall-off of the scattering atomic factors f_j with d^{-1} (or 2θ). This is in contrast with neutron-diffraction data, for which the scattering length does

Figure 3 Fitting of a part of the pattern of a sample of nanocrystalline ZnO, using pseudo-Voigt functions for modelling individual diffraction lines, $\text{CuK}\alpha_1$ radiation, $R_{\text{wp}}=1.2\%$. The observed intensity data are plotted as circles and the calculated pattern is shown as a continuous line. The lower trace is the difference curve. The $\times 10$ scale expansion shows the fit in the line-profile tails.

not fall off significantly over the range of observations. Another important difference between neutron and X-ray diffraction is that the relative scattering powers of atoms for neutrons and X-rays are significantly different. With neutrons there are pronounced differences in the scattering lengths of neighbouring elements. In the case of X-rays, there is a monotonic variation in X-ray scattering factors and hence light atoms are weak X-ray scatterers. For instance, in the case of $\text{U}(\text{UO}_2)(\text{PO}_4)_2$ the X-ray powder data are dominated by the U atom, the ratio of the scattering factors of U to O being greater than 11.5, while with neutrons oxygen is a relatively strong scatterer and then the ratio of the appropriate scattering lengths is 1.45. This property explains the major role played by neutron powder diffraction in determining oxygen content and position in high T_c cuprates in the presence of heavy atoms such as Ba, Hg, Tl and Bi.

Qualitative and Quantitative Analyses

Phase Identification

Qualitative phase identification is traditionally based on a comparison of observed data with interplanar spacings d and relative intensities I_0 compiled for crystalline materials. The Powder Diffraction File (PDF), edited by the International Centre for Diffraction Data (ICDD, www.icdd.com), contains powder data for more than 600 000 substances. It includes nearly as many inorganic as organic molecules. The Boolean search program supplied by the ICDD with the database offers great flexibility in phase identification and characterization. In a more

recent search/match procedure, complete digitized observed diffraction patterns are used, instead of simply a list of extracted d s and I s. To decide whether or not the pattern contains the data of a particular PDF entry, its data are compared with parts of zero intensity in the pattern for the unknown substance. The method can be used for multiphase patterns. As each phase is identified, the diffraction lines can be removed and the procedure is repeated by using the remaining regions of the pattern. The method is very efficient, even for the identification of minor phases if some known chemical constraints are introduced into the search.

Quantitative Phase Abundance

Quantitative phase analysis is the determination of the amounts of different phases present in a sample. The powder diffraction method is widely used to determine the abundance of distinct crystalline phases, e.g. in rocks and in mixtures of polymorphs, such as zirconia ceramics. The principle of the method is straightforward; the integrated intensity (I) of the diffraction lines from any phase in a mixture is proportional to the mass of the phase present in the sample. One analytical approach is based on a reference-intensity ratio (RIR) defined as the integrated intensity of the strongest reflection for the phase of interest to the strongest line of a standard (usually the 113 reflection of corundum) for a 1:1 mixture by weight. The measurement and use of RIRs is straightforward for materials for which the intensity does not vary with composition and preferred orientation. Because of the potential health hazard of respirable

Figure 4 Example of a typical Rietveld plot. The powder data of $\text{LiB}_2\text{O}_3(\text{OH}) \cdot \text{H}_2\text{O}$ were collected with the Debye–Scherrer (capillary) geometry using monochromatic $\text{CuK}\alpha_1$ radiation and a curved position-sensitive detector. The observed data are plotted as points and the calculated pattern as a continuous line. The lower trace is a plot of the difference of observed minus calculated. The vertical markers indicate the positions of calculated Bragg reflections. The intensity scale is magnified for the high-angle part, where the intensity of observed diffraction lines is low. Reprinted with permission of the International Union of Crystallography from Louër D, Louër M, and Touboul M (1992) Crystal structure determination of lithium diborate hydrate, $\text{LiB}_2\text{O}_3(\text{OH}) \cdot \text{H}_2\text{O}$, from X-ray powder diffraction data collected with a curved position-sensitive detector. *Journal of Applied Crystallography* 25: 617–623.

crystalline silica, X-ray powder diffraction is also used for detecting, identifying and quantifying the crystalline and amorphous silica of all types of samples from airborne dusts to bulk commercial products. SRMs 1878 (α -quartz) and 1979 (cristobalite) from NIST are certified with respect to amorphous content for analysis of silica-containing materials in accordance with health and safety regulations.

An extension of the Rietveld method is its application to multiphase samples for the determination of phase abundance. There is a simple relationship between the

individual scale factors determined in a Rietveld analysis and the weight fractions (W_i) of the phase concentration in a multicomponent mixture:

$$W_i = s_i(ZMV)_i / \sum_j s_j(ZMV)_j$$

where s_i , Z_i , M_i and V_i are the scale factor, the number of molecules per unit cell, the mass of the formula unit and the unit-cell volume of phase i , respectively and the summation is over all phases present. A requirement of the method is that the crystal structure is known for each

phase in the mixture. The use of all reflections in the selected angular range is a great advantage, since the uncertainty on phase abundance is reduced by minimizing preferred orientation effects. In general, phase-analysis results obtained with X-ray data are inferior to those obtained from neutron data. This is related to residual errors arising from an imperfect preferred orientation modelling and from microabsorption effects.

Ab Initio Structure Determination

Among the most recent advances of the powder method is the determination of crystal structures from powder diffraction data. It is an application for which the resolution of the pattern is of prime importance. A series of successive stages are involved in the analysis, including the determination of cell dimensions and identification of the space group from systematic reflection absences, the extraction of structure factor moduli $|F_{hkl}|$, the solution to the phase problem to elaborate a structure model and, finally, the refinement of the atomic coordinates with the Rietveld method.

Pattern Indexing

The purpose of pattern indexing is to reconstruct the three-dimensional reciprocal lattice of a crystalline solid from the radial distribution of lengths $d^* (=1/d)$ of the diffraction vectors. The basic equation used for indexing a powder diffraction pattern is obtained by squaring the reciprocal-lattice vectors $\mathbf{d}_{hkl}^* (=b^*a^* + kb^* + lc^*)$, expressed in terms of the basis vectors of the reciprocal lattice (a^* , b^* , c^*) and hkl Miller indices,

$$Q(hkl) = b^2 Q_A + k^2 Q_B + l^2 Q_C + 2klQ_D + 2blQ_E + 2bkQ_F$$

where $Q(hkl) = 1/d^2$, $Q_A = a^{*2}$, $Q_B = b^{*2}$, $Q_C = c^{*2}$, $Q_D = b^*c^* \cos \alpha^*$, $Q_E = c^*a^* \cos \beta^*$, $Q_F = a^*b^* \cos \gamma^*$; a^* , b^* , c^* are the linear parameters and α^* , β^* , γ^* the angles of the reciprocal unit cell. This quadratic form corresponds to the triclinic crystal symmetry. Only four parameters are required for a monoclinic cell, three for an orthorhombic cell, two for tetragonal and hexagonal cells, and one for a cubic cell. Indexing a powder pattern consists in finding the linear and angular dimensions of the unit cell, from which a set of Miller indices hkl can be assigned to each observed line Q_{obs} , within the experimental error on the observed peak positions. Automatic procedures are available to index a powder diffraction pattern. They are based on three main approaches, regardless of symmetry: the zone-indexing method, the index-permutation method and the successive-dichotomy method. The use of pattern-indexing methods requires a high precision on

peak positions ($|\Delta 2\theta| < 0.03^\circ 2\theta$). The assessment of the reliability of an indexed pattern is carried out with the de Wolff figure of merit M_{20} :

$$M_{20} = Q_{20}/2\langle \Delta Q \rangle N_{cal}$$

where Q_{20} corresponds to the 20th observed line, $\langle \Delta Q \rangle$ is the average absolute discrepancy between Q_{kobs} and the nearest Q_{kcal} value and N_{cal} is the number of distinct calculated Q values smaller than Q_{20} , not including any systematic absences if they are known. M_{20} is greater when $\langle \Delta Q \rangle$ is small and N_{cal} is as close as possible to 20. A related figure of merit, F_N , introduced for the evaluation of powder data quality, is also used. It is reported as 'value ($\langle \Delta 2\theta \rangle$, N_{cal})', where $\langle \Delta 2\theta \rangle$ is the average angular discrepancy. A solution with M_{20} greater than 20 is generally correct, although some geometrical ambiguities or the presence of a dominant zone can mask the true solution. An additional check of the reliability of the solution consists in indexing all measurable peak positions in the pattern, from which systematic absent reflections can be detected and, then, possible space groups are proposed. With synchrotron parallel-beam optics, higher figures of merit are obtained, since angular precision and resolution (more lines are observed) are considerably improved. There is no particular problem for indexing, from conventional X-ray data, patterns of materials with moderate cell volumes and, for instance, patterns of monoclinic compounds with volumes up to $3000 \text{ \AA}^3$ can be normally handled.

Structure Solution

Following the determination of the unit cell and space group assignment, integrated intensities (I_{hkl}) (or structure factor amplitudes) are extracted with a pattern-decomposition technique. For clusters of overlapping lines an equipartition of the overall intensity is generally applied. Therefore, intensity data sets contain a limited number of unambiguously measured reflections. An estimation of the proportion of statistically independent reflections can be calculated from an algorithm based on line width and reflection proximity. It is a useful indicator which depends on the selected angular range. The methods for solving the phase problem used with single-crystal data (Patterson methods and direct methods) are generally applicable with powder data. Computer programs have been adapted to the powder diffraction case. In general, only fragments of the structure are found from these methods; the remaining atoms are then obtained from subsequent Fourier calculations. However, with good data and a favourable proportion of unambiguous reflections, the success of the direct methods can be very high and even complete models (non-H atoms) may be revealed from one calculation.

Considerable effort has been devoted to the development of new approaches for the treatment of powder-diffraction data. They include the Monte Carlo and the simulated annealing approaches, the maximum-entropy method, the atom-atom potential method and genetic algorithms. Computer-modelling approaches operate in direct space. Trial crystal structures are generated independently of the observed powder diffraction data. The suitability of each structure model is assessed by comparison between the calculated and observed diffraction patterns and is quantified using an appropriate profile *R*-factor (see Table 3). The direct-space methods present the advantage of avoiding the critical stage of extracting the individual intensities from pattern decomposition. They are suitable for organic molecules, but a detailed knowledge of the expected molecule (bond lengths and torsional angles) is a basic requirement. An example is the structure determination of a metastable form of piracetam, $C_6H_{10}N_2O_2$, whose lifetime at room temperature is only 2 h, solved from powder data collected with a PSD (Figure 5). Structure determination from powder data is used in varied fields of materials science, including inorganic, organometallic and organic chemistry, mineralogy and pharmaceutical science. Although the analysis is generally applicable to moderately complex structures, it has been successful for solving structures containing, for instance, 29 atoms in the asymmetric unit, e.g. $Ga_2(HPO_3)_3 \cdot 4H_2O$, Ba_3AlF_3 , $Bi(H_2O)_4(OSO_2CF_3)_3$, or having a high unit-cell volume, e.g. $7471 \text{ \AA}^3$ for $[(CH_3)_4N]_4Ge_4S_{10}$. With the ultra-high resolution available with X-ray synchrotron radiation, determination of more complex structure can now be undertaken, particularly with materials containing light atoms.

For specific applications, the tunability of synchrotron radiation sources allows the X-ray wavelength to be changed readily, and this can be exploited to enhance the contrast between close elements in the periodic table. These studies are termed anomalous (resonant) scattering experiments. The atomic scattering factor for X-rays is defined as

$$f = f_0(\theta) + f'(E) + if''(E)$$

where f_0 varies only with $\sin \theta / \lambda$ and f' and f'' are the energy-dependent real and imaginary parts of the anomalous contribution. By selecting a wavelength close to the absorption edge of an element the scattering factor may change by a few electrons. By comparing powder data collected near-edge and off-edge, the technique can be used to determine the distribution of cations with similar atomic numbers over crystallographically distinct sites. Applications can be extended to mixed-oxidation states of an absorbing element if these are ordered within a crystal structure, e.g. Eu^{2+} and Eu^{3+} in Eu_3O_4 or Ga^{+} and Ga^{3+} in $GaCl_2$.

Figure 5 View of the crystal structure of a metastable phase of piracetam, $C_6H_{10}N_2O_2$, solved from the atom-atom potential method and refined with the Rietveld method. The crystal symmetry is monoclinic, space group $P2_1/n$ (the unit cell is shown with the *a* axis horizontal and *b* axis vertical) (crystal data are reported in *Acta Crystallographica* B51: 182, 1995). Powder diffraction data were collected from a conventional X-ray source.

Diffraction Line-Broadening Analysis

Microstructural imperfections (lattice distortions, stacking faults) and the small size of crystallites (i.e. domains over which diffraction is coherent) are usually extracted from the integral breadth or a Fourier analysis of individual diffraction line profiles. Lattice distortion (microstrain) represents a departure of atom positions from an ideal structure. Crystallite sizes covered in line-broadening analysis are in the approximate range 20–1000 Å. Stacking faults may occur in close-packed or layer structures, e.g. hexagonal Co and ZnO. The effect on line breadths is similar to that due to crystallite size, but there is usually a marked *bkl*-dependence. Fourier coefficients for a reflection of order *l*, $C(n, l)$, corrected from the instrumental contribution, are expressed as the product of real, order-independent, size coefficients $A^S(n)$ and complex, order-dependent, distortion coefficients $C^D(n, l) [=A^D(n, l) + iB^D(n, l)]$. Considering only the cosine coefficients $A(n, l) [=A^S(n) \cdot A^D(n, l)]$ and a series expansion of $A^D(n, l)$, $A^S(n)$ and the microstrain $\langle \epsilon^2(n) \rangle$ can be readily separated, if at least two orders of a

reflection are available, e.g. from the equation

$$A(n, l) = A^S(n) - A^S(n)2\pi^2 l^2 n^2 \langle e^2(n) \rangle$$

The inverse of the initial slope of the size coefficients $A^S(n)$ versus the Fourier harmonic number n (or $L=n/\Delta s$, where Δs is the range of the intrinsic profile in reciprocal units) is a measure of the Fourier apparent size, ε_F , defined as an area-weighted crystallite size. The second derivative of $A^S(n)$ is a measure of the crystallite size distribution in a direction perpendicular to the diffracting plane hkl , obtainable when strains are negligible. Fourier coefficients $C(n)$ are also related to the integral breadth, expressed in reciprocal units, $\beta^* [= \Delta s / \sum_n |C(n)|]$. For strain-free materials the reciprocal of this quantity is the integral-breadth apparent size, ε_β , defined as a volume-weighted thickness of a crystallite in the direction of the diffraction vector. For a spherical crystallite the direction of the diffraction vector is unimportant and there is a simple relation between the diameter D and ε_β ($=3D/4$) or ε_F ($=2D/3$). The ideal ratio $\varepsilon_\beta/\varepsilon_F$ is 1.125. Any departure from this ratio is due to the presence of a distribution of crystallite sizes. Similar expressions have been derived for other crystallite shapes, e.g. the cylinder, for which the two limiting cases are acicular and disk-like forms. Anisotropic models require precise determination of apparent sizes in various crystallographic directions. Representative examples of average spherical and cylindrical crystallite shapes are found in CeO_2 and ZnO loose powders.

These methods can be applied to more diffraction lines when profile-fitting techniques are employed, provided the observed data are precisely modelled. A more-detailed (three-dimensional) characterization of the microstructure can then be obtained. In the Fourier approach, line profiles must be reconstructed analytically, from the line-profile parameters extracted from pattern-decomposition techniques, prior to the physical interpretation. With the integral-breadth method, the use of Voigt functions in the modelling of observed b and instrumental g profiles represents a definitive advantage, since the integral breadth β_f of the intrinsic f profile can be precisely determined. Whatever the diffraction-line-broadening analysis employed, an essential preliminary step in the analysis is to examine a (Williamson–Hall) plot giving the variation of β_f (expressed in reciprocal units) as a function of d^* . Although this plot is not used for quantitative characterization, it gives an overview of the nature of the broadening due to sample imperfections and orients the subsequent analysis. **Figure 6** shows the hkl -dependence of the integral breadths for a sample of nanocrystalline ZnO . These plots can be varied according to the effects at the origin of line broadening and to their anisotropic nature. Since perfect modelling of line profiles are required in the Rietveld method, the technique

Figure 6 Example of a Williamson–Hall plot for a sample of nanocrystalline ZnO powder exhibiting size and stacking-fault diffraction line broadening according to the hkl values. (○) reflections unaffected by mistakes (hkl with l even, $h-k=3n$), (△) first reflection set affected by stacking faults (hkl with l odd, $h-k=3n\pm 1$), (■) second reflection set affected by stacking faults (hkl with l even, $h-k=3n\pm 1$).

can also, in principle, be used to extract microstructural properties. However, unless line broadening is isotropic, to obtain meaningful information the procedure must be able to handle the various possible sources of broadening present in the pattern, such as crystallite size, strain, stacking faults, dislocation density, and the residual errors related to the structure and preferred orientation models must be minimized.

Dynamic and Non-ambient Diffraction

Time and temperature dependent X-ray diffraction includes the measurement of a series of diffraction patterns as a function of time, temperature or other physical constraint. The time required for collecting data decreases considerably with the availability of fast detectors, such as PSDs, and the brightness of the X-ray source. In principle, line-profile parameters can be extracted for each pattern and interpreted in structural (peak position and integrated intensity) and microstructural (breadths and line shapes) terms. Consequently, the structural and microstructural changes taking place as a function of the external constraint (temperature, atmosphere, pressure, electric field, etc.) are displayed from the successive patterns. The method affords the possibility of establishing the pathways during chemical solid-state reactions, such as phase transition and thermal decomposition, and to determine the kinetics of processes, e.g. the crystallization of nanocrystalline solids or phase transformations. Patterns can be collected on a time scale of a few minutes with conventional X-rays but the high brightness of synchrotron

radiation makes it possible to measure diffraction data in very short time periods. A representative application is the investigation of fast and self-propagating solid combustion reactions on a subsecond time-scale. *In situ* powder diffraction can also be combined with other complementary techniques applied simultaneously, such as EXAFS (extended X-ray absorption fine structure). The two structural probes may provide long-range order information (powder diffraction) and short-range order details (EXAFS). For instance, *in situ* combined X-ray diffraction and EXAFS have been used for the study of the formation of heterogeneous catalysts.

Symbols

B_s	orthogonal base operator
E	unity operator
I_x, I_y, I_z	angular momentum operators
J	coupling constant
k, l, m	spin indices
N	number of spin- $\frac{1}{2}$ nuclei
q	number of operators in product
S_x, S_y, S_z	angular momentum operators
t_1	evolution time
t_2	acquisition time
θ	pulse angle
$\sigma(t)$	density operator
τ	duration of evolution
ϕ	pulse phase
ω	angular frequency of spin (nucleus)

The introduction of the product operator formalism by Ernst and co-workers can be regarded as one of the milestones in the development of NMR. Unusually, this is not because it constitutes an advance in either theory or technique, for it is neither, but because it makes it possible for many of the users of NMR to understand the experiments they carry out. It is necessary to use quantum mechanics to explain the behaviour of nuclear magnetism and a density operator to describe the state of the system. While this approach is rigorous, it can often appear abstract and lacking in physical intuition to those who do not have a background in quantum mechanics. Furthermore, calculations often involve cumbersome matrix operations. While there is an alternative in the physically intuitive net-magnetization vector model, this classical approach is only really useful for explaining very simple experiments such as the spin echo, and breaks down when it comes to explaining phenomena such as coherence transfer and multiple-quantum coherence that are ubiquitous in modern NMR spectroscopy. The product operator formalism provides a half-way house between the two approaches; it retains both the rigour of the density matrix and the physical intuition and ease of use of the vector model. While with the density matrix it is usual to follow the evolution of the system as a whole during the course of an experiment, with the product operator formalism the fate of individual components can easily be traced. The

product operator formalism can equally well be used either quantitatively to calculate the amplitude of the magnetization following particular coherence transfer pathways in the course of an experiment or qualitatively to sketch out those pathways. The product operator formalism has seen extensive use both as an education tool for explaining how NMR pulse sequences work and as a research tool used as an aid for designing new ones. Its main limitation is that it is really only suitable for describing weakly coupled spin systems. When multiple-quantum coherence is under consideration, it can be usefully supplemented with raising and lowering operators.

Theory

Origin and Definitions

The density operator $\sigma(t)$ can be expanded into a set of orthogonal base operators $\{B_s\}$:

$$\sigma(t) = \sum_{s=1}^{n^2} b_s(t) B_s \quad [1]$$

Product operators are one of many possible sets of base operators that can be chosen; the choice usually depends on the application. Product operators are based upon the angular momentum operators I_x , I_y and I_z of individual spins, and for spin- $\frac{1}{2}$ nuclei are defined by

$$B_s = 2^{(q-1)} \prod_{k=1}^N (I_{k\alpha})^{a_{ks}} \quad [2]$$

where N is the number of spin- $\frac{1}{2}$ nuclei in the spin system, k is the spin index, $\alpha = x, y$ or z , and q is the number of operators in the product. The coefficient a_{ks} has a value of 1 for spins in the product and 0 for all other spins.

For a system consisting of a single uncoupled spin k there are four possible product operators ($\frac{1}{2}$) E , I_{kz} , I_{kx} and I_{ky} , where E is the unity operator, which need not be considered further. The three remaining operators and their corresponding representations in the net-magnetization vector model are given in **Figure 1**. The operator I_{kz} corresponds to the k -spin z magnetization found at thermal equilibrium as a result of the Boltzmann distribution between the two spin states α and β . The operators I_{kx} and I_{ky} correspond to x and y components of k -spin magnetization in the xy plane. These two operators can also be described as the x and y components of the in-phase magnetization or as the

Figure 1 Vector model representations of one-spin and two-spin product operators arising from a spin k scalar coupled to a spin l . In the case of $2I_{kz}I_{lz}$ the l -spin vectors will be similarly arranged.

in-phase single-quantum coherence of spin k . The importance of making these qualifications will become apparent below. Neither I_{kx} nor I_{ky} is present at thermal equilibrium but they may be present after the application of a radiofrequency pulse to the equilibrium magnetization. The operators I_{kx} and I_{ky} are also important because they are the only operators that are directly observed in an NMR experiment; it is from these operators that the signal observed in the free induction decay arises.

Most systems of interest consists of more than one spin. The product operators for a two-spin system are listed in **Table 1**. Where applicable, representations of characteristic examples of these operators are given in the net-magnetization vector model in **Figure 1**. It should be noted that there are two methods for differentiating between spins. Different subscripts, k and l in the operator $2I_{kz}I_{lz}$, are commonly used to denote different spins in homonuclear systems, while in heteronuclear systems the operators themselves may be denoted by different letters, I and S in the operator $2I_zS_z$. In the latter case I is usually taken to denote ^1H . In the case of a doublet, longitudinal two-spin order arises when the equilibrium magnetization of one of its two transitions has been inverted. Antiphase magnetization arises when the two components of the doublet point in opposite directions in the xy plane. The longitudinal component of the operator indicates the scalar coupling that separates the two components of the multiplet with opposite phases. The four operators denoting two-spin coherence consist of linear combinations

Table 1 Product operators for two spin- $\frac{1}{2}$ nuclei

Product operator	Description
$\frac{1}{2}E$	E = unity operator
I_{kx}, I_{ky}	In-phase x magnetization and y magnetization, respectively, of spin k
I_{lx}, I_{ly}	In-phase x magnetization and y magnetization, respectively, of spin l
I_{kz}, I_{lz}	Longitudinal magnetization of spins k and l , respectively
$2I_{kx}I_{lz}, 2I_{ky}I_{lz}$	x and y components, respectively, of k -spin magnetization antiphase with respect to l
$2I_{kx}I_{lx}, 2I_{kx}I_{ly}, 2I_{ky}I_{lx}, 2I_{ky}I_{ly}$	Components of two-spin coherence between spins k and l
$2I_{kz}I_{lz}$	Longitudinal two-spin order between k and l

of zero-quantum and double-quantum coherence; these will be considered below.

Evolution

The evolution of product operators can be calculated in a similar way to that of the density matrix, by a series of transformations of the type

$$\exp\{-i\phi B_r\} B_s \exp\{i\phi B_r\} = \sum_t b_{ts}(r, \phi) B_t \quad [3]$$

where ϕB_r corresponds to the relevant Hamiltonian. This takes the form $(\omega_k \tau) I_{kz}$ for chemical shift evolution of a

spin k for a period τ , $(\pi J_{kl}\tau)2I_{kz}I_{lz}$ for scalar coupling evolution between two weakly coupled spins k and l for a period τ , and $(\beta)I_{kx}$ for a radiofrequency pulse applied to a spin k producing a rotation of β about the x axis. In each case the bracket has been added to indicate the angle through which the affected operators will evolve. Since all terms in the free precession Hamiltonian commute, the evolution of individual chemical shifts and scalar couplings in multispin systems can be treated separately and in any order. In general, each process causes a rotation in a subspace (**Figure 2**), corresponding to the evolution of one operator into another. In the case of a β_x° pulse applied to the equilibrium magnetization of a spin k , a component of the magnetization may be rotated onto the y axis:

$$I_{kz} \xrightarrow{\beta I_{kx}} I_{kz} \cos \beta - I_{ky} \sin \beta \quad [4]$$

A vector description of this process is given in **Figure 3**. However, a β_x° pulse has no effect on I_{kx} :

$$I_{kx} \xrightarrow{\beta I_{kx}} I_{kx} \quad [5]$$

It is important to use the correct sign conventions, which are given in **Figure 2**. If a pulse acts on a product of several operators, its overall effect can be determined

by calculating its effects on each individual operator and then multiplying out the results. For example

$$\begin{aligned} 2I_{kz}I_{lz} &\xrightarrow{\beta(I_{kx}+I_{lx})} 2(I_{kz} \cos \beta - I_{ky} \sin \beta) \\ &\quad \times (I_{lz} \cos \beta - I_{ly} \sin \beta) \\ &\equiv 2I_{kz}I_{lz} \cos^2 \beta \\ &\quad - 2I_{kz}I_{ly} \cos \beta \sin \beta - 2I_{ky}I_{lz} \sin \beta \\ &\quad \times \cos \beta + 2I_{ky}I_{ly} \sin^2 \beta \end{aligned} \quad [6]$$

Where a pulse affects all of the nuclear spins under consideration the shorthand ' β_x° ' is often written over the arrow.

Chemical shift evolution may be expressed in a similar fashion to that of radiofrequency pulses. For example, the chemical shift evolution of the operator I_{ky} at a frequency of ω_k over a period τ can be written as

$$I_{ky} \xrightarrow{\omega_k \tau I_{kz}} I_{ky} \cos \omega_k \tau - I_{kx} \sin \omega_k \tau \quad [7]$$

A vector model representation of this process is given in **Figure 3**.

Scalar coupling evolution results in the interconversion of components of in-phase and antiphase magnetization. In the case of a component of in-phase k -spin

Figure 2 Sign conventions for product operator evolution under radiofrequency pulse, chemical shift and scalar coupling evolution.

Figure 3 Vector model representations of the evolution of k -spin magnetization. (a) The effect of a β_x pulse on z magnetization. (b) The effect of chemical shift evolution for a time τ on y magnetization. (c) The effect of scalar coupling evolution for a time τ on y magnetization.

magnetization I_{ky} evolution due to a scalar coupling to a spin l during a period τ can be described by

$$I_{ky} \xrightarrow{\pi J_{kl} \tau 2 I_{kz} I_{lz}} I_{ky} \cos \pi J_{kl} \tau - 2 I_{kx} I_{lz} \sin \pi J_{kl} \tau \quad [8]$$

This is represented pictorially in **Figure 3**. If the spin k is scalar coupled to a further spin m , the effects of evolution due to the two scalar couplings can be calculated sequentially:

$$\begin{aligned} I_{ky} &\xrightarrow{\pi J_{kl} \tau 2 I_{kz} I_{lz}} I_{ky} \cos \pi J_{kl} \tau - 2 I_{kx} I_{lz} \sin \pi J_{kl} \tau \\ &\xrightarrow{\pi J_{km} \tau 2 I_{kz} I_{mz}} I_{ky} \cos \pi J_{kl} \tau \cos \pi J_{km} \tau \\ &\quad - 2 I_{kx} I_{mz} \cos \pi J_{kl} \tau \sin \pi J_{km} \tau \\ &\quad - 2 I_{kx} I_{lz} \sin \pi J_{kl} \tau \cos \pi J_{km} \tau \\ &\quad - 4 I_{ky} I_{lz} I_{mz} \sin \pi J_{kl} \tau \sin \pi J_{km} \tau \end{aligned} \quad [9]$$

The term $4 I_{ky} I_{lz} I_{mz}$ corresponds to a y component of doubly antiphase k -spin magnetization; it is antiphase with respect to both l and m . It is important to note that if a component of magnetization has become antiphase with respect to one spin, scalar coupling evolution with

respect to another spin will not make it in-phase again; only a further period during which evolution occurs due to the first spin's scalar coupling will have that effect.

Multiple-Quantum Coherence

The components of transverse magnetization considered above are all what are known as single-quantum coherences. Single-quantum coherences are phase coherences between states differing in overall magnetic quantum number by ± 1 . Phase coherences between states that do not fulfil this criterion are known as multiple-quantum coherence. Multiple-quantum coherences cannot be created by the application of a single nonselective radiofrequency pulse to the equilibrium magnetization and neither can they be detected directly since they have no net magnetization associated with them. Nevertheless, multiple-quantum coherences play an important role in many NMR experiments. The product operators $2 I_{ky} I_{lx}$, $2 I_{kx} I_{ly}$, $2 I_{ky} I_{ly}$ and $2 I_{kx} I_{lx}$ all describe linear combinations of multiple-quantum coherences; however, their precise meaning only becomes apparent when they are rewritten in terms of

raising and lowering operators:

$$I_{kx} = \left(\frac{1}{2}\right)(I_k^+ + I_k^-) \quad [10]$$

$$I_{ky} = \left(\frac{1}{2i}\right)(I_k^+ - I_k^-) \quad [11]$$

The operators I_k^+ and I_k^- are counterrotating components corresponding to $+1$ and -1 quantum coherence, respectively; the former precesses at a frequency of $+\omega_k$ and the latter at a frequency of $-\omega_k$. Re-writing $2 I_{ky}I_{lx}$ in terms of raising and lowering operators we find that

$$2I_{ky}I_{lx} = \left(\frac{1}{2i}\right)(I_k^+I_l^+ + I_k^+I_l^- - I_k^-I_l^+ - I_k^-I_l^-) \quad [12]$$

Clearly, $2I_{ky}I_{lx}$ consists of a linear combination of $+2$, 0 , and -2 quantum coherence. The other three operators can be re-written in a similar fashion. Pure zero-quantum coherence (ZQC) and double-quantum coherence (DQC) can be isolated by taking linear combinations of these four product operators:

$$ZQC_x = \left(\frac{1}{2}\right)(2I_{kx}I_{lx} + 2I_{ky}I_{ly}) = \left(\frac{1}{2}\right)(I_k^+I_l^- + I_k^-I_l^+) \quad [13]$$

$$ZQC_y = \left(\frac{1}{2}\right)(2I_{kx}I_{ly} - 2I_{ky}I_{lx}) = \left(\frac{1}{2i}\right)(I_k^+I_l^- - I_k^-I_l^+) \quad [14]$$

$$DQC_x = \left(\frac{1}{2}\right)(2I_{kx}I_{lx} - 2I_{ky}I_{ly}) = \left(\frac{1}{2}\right)(I_k^+I_l^+ - I_k^-I_l^-) \quad [15]$$

$$DQC_y = \left(\frac{1}{2}\right)(2I_{kx}I_{ly} + 2I_{ky}I_{lx}) = \left(\frac{1}{2i}\right)(I_k^+I_l^+ - I_k^-I_l^-) \quad [16]$$

The spins involved in a coherence, in this case k and l , are often referred to as the active spins. The evolution of these x and y components of multiple-quantum coherences can be calculated in the same fashion as single-quantum coherence (I_{kx} and I_{ky}) with several important provisos:

- (1) The precessional frequency of a multiple-quantum coherence is a linear combination of those of its active spins. A double-quantum coherence with active spins k and l will evolve at $(\omega_k + \omega_l)$, while the corresponding zero-quantum coherence will evolve at $(\omega_k - \omega_l)$.
- (2) Multiple-quantum coherences do not exhibit scalar couplings between their active spins. Their scalar couplings to passive spins are linear combinations of those of their individual active spins to the passive spin concerned. Thus a double-quantum coherence between spins k and l would exhibit a scalar coupling constant of $(J_{km} + J_{lm})$ to a passive spin m ; the corresponding zero-quantum coherence scalar coupling constant would be $(J_{km} - J_{lm})$.

Consequently, the chemical shift evolution of the y component of a zero-quantum coherence with active

spins k and l during a period τ can be written as

$$ZQC_y \xrightarrow{(\omega_k I_{kz} + \omega_l I_{lz})\tau} ZQC_y \cos(\omega_k - \omega_l)\tau - ZQC_x \sin(\omega_k - \omega_l)\tau \quad [17]$$

and the scalar coupling evolution of the corresponding double-quantum coherence to passive spin m can be described by

$$DQC_y \xrightarrow{(\pi J_{km} 2I_{kz} I_{mz} + \pi J_{lm} 2I_{lz} I_{mz})\tau} DQC_y \cos(J_{km} + J_{lm})\pi\tau - DQC_x 2I_{mz} \times \sin(J_{km} + J_{lm})\pi\tau \quad [18]$$

Applications

The product operator formalism has been used to analyse most liquid-state NMR experiments since it was first introduced in 1983. The examples given here have been chosen either because of the way in which they exemplify the manipulation of product operators or because the pulse sequences concerned play an important role in contemporary NMR spectroscopy. The spin echo is considered because of its wide use and the opportunity it presents to undertake a relatively simple product operator calculation in full without resort to any of the short cuts that will be used to simplify later calculations. COSY (correlation spectroscopy) is also a widely used experiment and allows the introduction of the concept of coherence transfer, and its double-quantum filtered variant exemplifies some important points about how multiple-quantum coherence is handled in product operator calculations. The HSQC (heteronuclear single-quantum coherence) pulse sequence is widely used as a basis for many heteronuclear experiments, particularly for structural studies of proteins in solution, and DEPT (distortionless enhanced polarization transfer) is one of the mainstays of perhaps the largest group of NMR users, organic chemists.

Spin Echo

The spin echo is important both as an experiment in its own right for measuring transverse relaxation and as a building block of numerous other pulse sequences. The spin echo pulse sequence is

$$90_x^\circ - \tau - 180_y^\circ - \tau - \text{Acquisition}$$

The properties of this pulse sequence can be determined using the product operator formalism. Its effects on the equilibrium magnetization of a spin k with a scalar coupling to a spin l are calculated below. As an exercise

the intermediate steps in the calculation are given in full (see eqn [19] below).

In the remaining examples given below, the product operators will only be given at key stages during an ex-

$$\begin{aligned}
 I_{kz} &\xrightarrow{90_x^\circ} -I_{ky} \xrightarrow{\omega_k t_{kz}} -I_{ky} \cos(\omega_k \tau) + I_{kx} \sin(\omega_k \tau) \\
 &\quad \downarrow \pi J_{kl} \tau 2I_z \cdot I_l \\
 &\quad I_{ky} \cos(\omega_k \tau) \cos(\pi J_{kl} \tau) + I_{kx} \sin(\omega_k \tau) \cos(\pi J_{kl} \tau) \\
 &\quad + 2I_{kx} I_{lz} \cos(\omega_k \tau) \sin(\pi J_{kl} \tau) + 2I_{ky} I_{lz} \sin(\omega_k \tau) \sin(\pi J_{kl} \tau) \\
 &\quad \downarrow \text{ISO}_y \\
 &\quad I_{ky} \cos(\omega_k \tau) \cos(\pi J_{kl} \tau) + I_{kx} \sin(\omega_k \tau) \cos(\pi J_{kl} \tau) \\
 &\quad + 2I_{kx} I_{lz} \cos(\omega_k \tau) \sin(\pi J_{kl} \tau) - 2I_{ky} I_{lz} \sin(\omega_k \tau) \sin(\pi J_{kl} \tau) \\
 &\quad \downarrow \omega_k t_{kx} \\
 &\quad -I_{ky} \cos^2(\omega_k \tau) \cos(\pi J_{kl} \tau) - I_{kx} \sin(\omega_k \tau) \cos(\pi J_{kl} \tau) \cos(\omega_k \tau) \\
 &\quad + 2I_{kx} I_{lz} \cos^2(\omega_k \tau) \sin(\pi J_{kl} \tau) - 2I_{ky} I_{lz} \sin(\omega_k \tau) \sin(\pi J_{kl} \tau) \cos(\omega_k \tau) \\
 &\quad + I_{kx} \cos(\omega_k \tau) \cos(\pi J_{kl} \tau) \sin(\omega_k \tau) - I_{ky} \sin(\omega_k \tau)^2 \cos(\pi J_{kl} \tau) \\
 &\quad + 2I_{ky} I_{lz} \cos(\omega_k \tau) \sin(\pi J_{kl} \tau) \sin(\omega_k \tau) + 2I_{kx} I_{lz} \sin^2(\omega_k \tau) \sin(\pi J_{kl} \tau) \\
 &\quad \downarrow \pi J_{kl} \tau 2I_z \cdot I_l \\
 &\quad -I_{ky} \cos^2(\omega_k \tau) \cos^2(\pi J_{kl} \tau) - I_{kx} \sin(\omega_k \tau) \cos^2(\pi J_{kl} \tau) \cos(\omega_k \tau) \\
 &\quad - 2I_{kx} I_{lz} \cos^2(\omega_k \tau) \sin(\pi J_{kl} \tau) \cos(\pi J_{kl} \tau) - 2I_{ky} I_{lz} \sin(\omega_k \tau) \sin(\pi J_{kl} \tau) \cos(\omega_k \tau) \cos(\pi J_{kl} \tau) \\
 &\quad + I_{kx} \cos(\omega_k \tau) \cos(\pi J_{kl} \tau) \sin(\omega_k \tau) \cos(\pi J_{kl} \tau) - I_{ky} \sin(\omega_k \tau)^2 \cos^2(\pi J_{kl} \tau) \\
 &\quad + 2I_{ky} I_{lz} \cos(\omega_k \tau) \sin(\pi J_{kl} \tau) \sin(\omega_k \tau) \cos(\pi J_{kl} \tau) + 2I_{kx} I_{lz} \sin^2(\omega_k \tau) \sin(\pi J_{kl} \tau) \cos(\pi J_{kl} \tau) \\
 &\quad + I_{kx} I_{lz} \cos^2(\omega_k \tau) \cos(\pi J_{kl} \tau) \sin(\pi J_{kl} \tau) - 2I_{ky} I_{lz} \sin(\omega_k \tau) \cos(\pi J_{kl} \tau) \cos(\omega_k \tau) \sin(\pi J_{kl} \tau) \\
 &\quad + I_{ky} \cos^2(\omega_k \tau) \sin^2(\pi J_{kl} \tau) + I_{kx} \sin(\omega_k \tau) \sin^2(\pi J_{kl} \tau) \cos(\omega_k \tau) \\
 &\quad + 2I_{ky} I_{lz} \cos(\omega_k \tau) \cos(\pi J_{kl} \tau) \sin^2(\omega_k \tau) + 2I_{kx} I_{lz} \sin(\omega_k \tau)^2 \cos(\pi J_{kl} \tau) \sin(\pi J_{kl} \tau) \\
 &\quad - I_{kx} \cos(\omega_k \tau) \sin(\pi J_{kl} \tau) \sin(\omega_k \tau) \sin(\pi J_{kl} \tau) + I_{ky} \sin^2(\omega_k \tau) \sin^2(\pi J_{kl} \tau) \\
 &= I_{ky} \cos(2\pi J_{kl} \tau) + 2I_{kx} I_{lz} \sin(2\pi J_{kl} \tau)
 \end{aligned} \tag{19}$$

It can be seen from the above that the product operators for even very simple systems can proliferate rapidly. Consolidation reduces the 16 terms present at the end of the calculation to two. It can be seen from the result that overall there is no evolution due to chemical shift (and by implication the effects of magnetic field inhomogeneities), which makes the pulse sequence useful for measuring transverse relaxation. However, scalar coupling evolution continues unaffected. In reality, it is rarely necessary to undertake a calculation of such complexity; the results of standard pulse sequences such as the spin echo are well known, so it is only necessary to write

$$\begin{aligned}
 I_{kz} &\xrightarrow{90_x^\circ} -I_{ky} \xrightarrow{\tau, 180_y^\circ, \tau} -I_{ky} \cos(2\pi J_{kl} \tau) \\
 &\quad + 2I_{kx} I_{lz} \sin(2\pi J_{kl} \tau)
 \end{aligned} \tag{20}$$

periment and any not following the selected coherence transfer pathway (and which are not observed) will be omitted.

COSY

The COSY experiment has become one of the mainstays of modern NMR spectroscopy; it is also one of the simplest two-dimensional experiments:

$$90_x^\circ - t_1 - 90_\phi^\circ - \text{Acquisition}$$

where $\phi = x, y$. The value of ϕ determines whether the $\sin(\omega_k t_1)$ or the $\cos(\omega_k t_1)$ modulated component of the data is observed; it is necessary to measure both if absorptive phase-sensitive spectra are to be obtained. The coherence transfer pathways detected in each case are given below. The magnetization of a spin k coupled to a

spin l is considered. When $\phi = y$:

$$\begin{aligned}
 I_{kz} \xrightarrow{90^\circ_x} I_{ky} \xrightarrow{t_1} & I_{ky} \cos \omega_k t_1 \cos \pi J_{kl} t_1 \\
 & + 2I_{kx} I_{lz} \cos \omega_k t_1 \sin \pi J_{kl} t_1 \\
 & \downarrow 90^\circ_z \\
 & - I_{ky} \cos \omega_k t_1 \cos \pi J_{kl} t_1 \\
 & - 2I_{kz} I_{ly} \cos \omega_k t_1 \sin \pi J_{kl} t_1 \quad [21]
 \end{aligned}$$

and when $\phi = x$:

$$\begin{aligned}
 I_{kz} \xrightarrow{90^\circ_x} -I_{ky} \xrightarrow{t_1} & -I_{kx} \sin \omega_k t_1 \cos \pi J_{kl} t_1 \\
 & + 2I_{ky} I_{lz} \sin \omega_k t_1 \sin \pi J_{kl} t_1 \\
 & \downarrow 90^\circ_z \\
 & - I_{kx} \sin \omega_k t_1 \cos \pi J_{kl} t_1 \\
 & - 2I_{kz} I_{ly} \sin \omega_k t_1 \sin \pi J_{kl} t_1 \quad [22]
 \end{aligned}$$

These equations provide an introduction to the concept of coherence transfer, the process by which one coherence is transformed into another. In each case a component of k -spin magnetization is transformed into l -spin magnetization. In the first equation the coherence transfer process, brought about by the second 90° pulse, is

$$2I_{kx} I_{lz} \xrightarrow{90^\circ_z} -2I_{kz} I_{lx} \quad [23]$$

Coherence transfer plays a central role in many NMR experiments and usually involves antiphase magnetization. The components of in-phase magnetization present at the end of the schemes above have evolved at ω_k during t_1 and will evolve at ω_k during the acquisition time t_2 ; consequently they will give rise to a diagonal COSY peak with the coordinates (ω_k, ω_k) . However, the antiphase magnetization will have evolved at ω_k during t_1 , but since it underwent coherence transfer from k to l at the second 90° pulse it will evolve at ω_l during the acquisition period. Consequently it will give rise to an off-diagonal peak in the COSY spectrum at the coordinates (ω_k, ω_l) . The components of magnetization giving rise to the diagonal and off-diagonal peaks are 90° out of phase; I_{ky} and $2I_{kz} I_{lx}$ in the case of the $\cos(\omega_k t_1)$ modulated components. This leads to diagonal peaks that are always dispersive when the off-diagonal peaks are phased to be absorptive, and vice versa.

Double-Quantum Filtered COSY

Double-quantum filtered COSY is a widely used version of the COSY experiment. It has two main advantages over its precursor: diagonal and off-diagonal peaks can be phased to be absorptive simultaneously, and singlets are removed from the spectrum. The pulse sequence is

$$90^\circ_x - t_1 - 90^\circ_\phi - 90^\circ_x - \text{Acquisition}$$

where $\phi = x, y$ to select both $\sin(\omega_k t_1)$ and $\cos(\omega_k t_1)$ modulated components of the data. The selected pathway followed by the magnetization of a spin k with a single scalar coupling partner l is given below. When $\phi = x$:

$$\begin{aligned}
 I_{kz} \xrightarrow{90^\circ_z} -I_{ky} \xrightarrow{t_1} & + 2I_{kx} I_{lz} \cos \omega_k t_1 \sin \pi J_{kl} t_1 \\
 & \downarrow 90^\circ_x \\
 & \left(\frac{1}{2}\right) (2I_{ky} I_{lx} + 2I_{kx} I_{ly}) \cos \omega_k t_1 \sin \pi J_{kl} t_1 \\
 & \downarrow 90^\circ_z \\
 & \left(\frac{1}{2}\right) (2I_{kz} I_{ly} + 2I_{kx} I_{lz}) \cos \omega_k t_1 \sin \pi J_{kl} t_1 \quad [24]
 \end{aligned}$$

and when $\phi = y$:

$$\begin{aligned}
 I_{kz} \xrightarrow{90^\circ_z} -I_{ky} \xrightarrow{t_1} & + 2I_{ky} I_{lz} \sin \omega_k t_1 \sin \pi J_{kl} t_1 \\
 & \downarrow 90^\circ_y \\
 & \left(\frac{1}{2}\right) (2I_{ky} I_{lx} + 2I_{kx} I_{ly}) \sin \omega_k t_1 \sin \pi J_{kl} t_1 \\
 & \downarrow 90^\circ_z \\
 & \left(\frac{1}{2}\right) (2I_{kz} I_{lx} + 2I_{kx} I_{ly}) \sin \omega_k t_1 \sin \pi J_{kl} t_1 \quad [25]
 \end{aligned}$$

The second 90° pulse actually creates $2I_{ky} I_{lx}$ or $2I_{kx} I_{ly}$, depending on ϕ . However, phase cycling (or magnetic field gradient pulses) selects only that component of the operator corresponding to double-quantum coherence. Using eqns [13]–[16], these operators can be resolved into components of zero-quantum and double-quantum coherence. For example, in the case of $2I_{ky} I_{lx}$:

$$2I_{ky} I_{lx} = \left(\frac{1}{2}\right) (2I_{ky} I_{lx} + 2I_{kx} I_{ly}) + \left(\frac{1}{2}\right) (2I_{ky} I_{lx} - 2I_{kx} I_{ly}) \quad [26]$$

where the first linear combination on the right of the equation consists of pure double-quantum coherence and the second pure zero-quantum coherence. The diagonal and off-diagonal peaks now both arise from components of antiphase magnetization with the same phase.

HSQC

The HSQC (heteronuclear single-quantum coherence) pulse sequence is an important tool in heteronuclear ^1H – ^{15}N and ^1H – ^{13}C NMR spectroscopy, particularly for larger molecules such as proteins. The pulse sequence is

The product operator description for a $^{13}\text{CH}_2$ group is the same except for the last three steps:

$$\begin{aligned}
 I_z &\xrightarrow{90^\circ_x(I), \left(\frac{1}{2J_{\text{CH}}}\right), 90^\circ_z(S)} -2I_xS_y \xrightarrow{\left(\frac{1}{2J_{\text{CH}}}\right)} \\
 + 4I_xS_yI_z &\xrightarrow{\theta_y^\circ(I), 180^\circ_z(S)} 4I_zS_yI_z \sin\theta \cos\theta \\
 &\downarrow \left(\frac{1}{2J_{\text{CH}}}\right) \\
 &-S_x \sin\theta \cos\theta \quad [29]
 \end{aligned}$$

In this case the two-spin coherences generated by the $90^\circ(S)$ pulse both exhibit large scalar couplings to the remaining proton in the $^{13}\text{CH}_2$ group. These are $(J_{\text{CH}} - J_{\text{HH}})$ and $(J_{\text{CH}} + J_{\text{HH}})$ for the zero-quantum and double-quantum coherences, respectively. However, since scalar couplings are ineffective between equivalent spins, this reduces to J_{CH} in each case. Consequently, the operator evolves to become completely antiphase with respect to the remaining proton in the $^{13}\text{CH}_2$ group during the subsequent $(1/2J_{\text{CH}})$ period. This time the observed magnetization has a $\sin\theta \cos\theta$ dependence on the subsequent ^1H pulse.

For a $^{13}\text{CH}_3$ group:

$$\begin{aligned}
 I_z &\xrightarrow{90^\circ_x(I), \left(\frac{1}{2J_{\text{CH}}}\right), 90^\circ_z(S)} -2I_xS_y \xrightarrow{\left(\frac{1}{2J_{\text{CH}}}\right)} \\
 + 8I_xS_yI_zI_z &\xrightarrow{\theta_y^\circ(I), 180^\circ_z(S)} 8I_zS_yI_zI_z \sin\theta \cos^2\theta \\
 &\downarrow \left(\frac{1}{2J_{\text{CH}}}\right) \\
 &-S_x \sin\theta \cos^2\theta \quad [30]
 \end{aligned}$$

The two-spin coherences generated by the $90^\circ(S)$ pulse exhibit scalar couplings of J_{CH} to the two remaining protons in the $^{13}\text{CH}_2$ group and consequently evolve to become antiphase with respect to both of them during the subsequent $(1/2J_{\text{CH}})$ period. As a result, the observed magnetization will exhibit a $\sin\theta \cos^2\theta$ dependence. Since each group has a different dependence on the θ° pulse, it is possible to isolate the subspectra arising from each group by acquiring data with three values of θ and taking the appropriate linear combinations of the results.

Introduction

The first ^1H NMR (nuclear magnetic resonance) spectrum of a protein, ribonuclease, was published in 1957; this spectrum, collected at 40 MHz, accurately reflected the amino acid composition but had neither the sensitivity nor the resolution to yield further information. In more than 50 years since then, solution NMR has become an extremely important technique for the study of protein structure, dynamics, activity, and folding. The first structure of a protein determined by solution NMR was reported in 1984, and since then structures of more than 3000 proteins (of > 50 amino acids) have been deposited in the Protein Data Bank. Advances in NMR of proteins became possible as a result of the concurrent development of higher-field (500–950 MHz) superconducting magnets, powerful computational hardware and software, complex multidimensional heteronuclear NMR experiments, cryogenically cooled probes, and overexpression of proteins in microorganisms allowing isotopic labeling. The quest for structural information has been driven by the recognition that functions of biologically active proteins (such as enzymes, hormones, and receptors) are fundamentally dependent on their three-dimensional (3-D) structure. The development of NMR techniques, in parallel with X-ray crystallography, to obtain greater structural information from increasingly complex protein systems has resulted in increased understanding of biological processes. NMR also has a role in the characterization of protein interactions via, for example, titrations that map the binding surface of a protein through specific chemical shift changes. These binding studies, which are discussed in this encyclopedia, as listed in the ‘See also’ list,

benefit from prior characterization of solution structure by NMR, and it is the structural aspects of protein NMR that are the focus of the present article. The theory and practical aspects of many areas of NMR spectroscopy important to protein NMR studies are described in detail elsewhere in this encyclopedia; these are consequently mentioned only briefly here. Protein NMR has been thoroughly documented in many books and reviews, and for more detailed discussion the reader is directed to the ‘Further Reading’ section.

What Proteins Are Suitable for Study by NMR?

Full structural characterization of small proteins (up to ~ 100 amino acids) in solution is possible using homonuclear ^1H NMR, but such studies are less common today due to the relative ease with which ^{15}N and ^{13}C can be incorporated into recombinant proteins. For larger proteins, of up to ~ 20 – 30 kDa, isotopic enrichment with ^{15}N and ^{13}C is required. Incorporation of ^2H can push the molecular weight limit beyond 30 kDa in favorable cases. There is no clear ‘cut-off’ in terms of protein size; each protein has to be considered on its own merits. Proteins must be nonaggregated and monomeric, or at least not present as large heteromultimers, under conditions of NMR measurements. Aggregated proteins give increased line widths and thus reduced spectral resolution and sensitivity. Often, the likelihood of a successful structure determination only becomes clear after considerable protein purification and preliminary one-dimensional (1-D) ^1H NMR data have been obtained.

Protein Structure

Proteins are composed of a linear sequence of L-amino acid residues linked via amide bonds. The 20 naturally occurring amino acids are distinguished by the chemical nature of their side chains. The amide bonds, or peptide linkages, are essentially planar and provide structural rigidity to the protein backbone, the only freedom to rotate being around the bonds to C^α . The angles of rotation are called, in IUPAC nomenclature, ϕ for the $\text{N}-\text{C}^\alpha$ bond $[\text{C}(\text{O})_{i-1}-\text{N}_i-\text{C}_i^\alpha-\text{C}(\text{O})_i]$ and ψ for the $\text{C}^\alpha-\text{C}(\text{O})$ bond $[\text{N}_i-\text{C}_i^\alpha-\text{C}(\text{O})_i-\text{N}_{i+1}]$ (Figure 1). If these two torsion angles are known for each amino acid then the conformation of the whole polypeptide backbone is defined.

Figure 1 Representation of a portion of a polypeptide chain, indicating the nomenclature of the backbone torsion angles (ϕ and ψ) and the side-chain torsion angle (χ_1) for the bonds emanating from the α carbon of an amino acid residue (i).

The linear sequence of amino acids represents the primary structure of the protein. Local regions within this structure can adopt stable, defined, secondary structure such as α -helices and β -sheets. The packing of these secondary structure elements into compact domains gives rise to the protein's tertiary structure, such that distant regions of the polypeptide chain can be spatially close together. Multimeric proteins are composed of several polypeptide chains arranged together in a quaternary structure. Adoption of the correct tertiary and quaternary structure is usually essential for biological function of a protein, and a central dogma of biochemistry is that knowledge of a protein's structure leads to a better understanding of its activity.

Labeling of Proteins with ^{15}N , ^{13}C , and ^2H

The range of proteins that can be studied by NMR and the nature of the structural information available have been extended through the biosynthetic incorporation of ^{15}N , ^{13}C , and ^2H isotopes. ^{15}N or ^{13}C are used as an indirectly-detected dimension in multidimensional heteronuclear experiments. Deuteration leads to increased T_2 values for $^{13}\text{C}^\alpha$, $^{13}\text{C}^\beta$, and $^1\text{H}^\text{N}$; this is important in studies of larger proteins.

Most proteins for structural analysis are prepared in cultures of bacteria or yeast that have been genetically modified to overexpress the protein of interest. Typically, 20–100 mg of protein is required for a structural NMR study. *Escherichia coli* (*E. coli*) bacteria are preferentially used as they can be grown rapidly in large quantities on chemically defined media that can be supplemented with ^{15}N -labeled ammonium salts and ^{13}C -labeled

compounds, such as glucose, acetate, or glycerol. It is essential to exclude all sources of natural-abundance nitrogen and carbon from growth media to maximize incorporation of isotopic label. Growth of *E. coli* in media prepared with 99.8% deuterium oxide ($^2\text{H}_2\text{O}$) can result in protein with up to $\sim 85\%$ deuteration; this is often sufficient to increase ^{13}C and $^1\text{H}^{\text{N}}$ T_2 values significantly. Higher levels of deuteration require the use of 99.8% $^2\text{H}_2\text{O}$ and ^{13}C - ^2H -glucose. The activity of expressed proteins should be validated to ensure correct folding.

Preparation of Protein Samples for NMR

A typical sample for protein NMR will contain 0.3–1 mM protein, of high purity, in 0.3–0.6 ml of aqueous solution. The final stages of purification may include desalting, buffer exchange, $^2\text{H}_2\text{O}$ exchange and concentration by lyophilization (if the protein is sufficiently stable), vacuum centrifugation, or ultrafiltration.

Data collection can take several days, during which the protein must remain stable; therefore, oxidation, hydrolysis, and microbial contamination must be minimized. Samples are not usually degassed, as protein solutions tend to 'froth,' and paramagnetic broadening by oxygen can usually be ignored. The growth of microorganisms can be prevented by sodium azide.

The quality of NMR spectra of proteins can be strongly influenced by sample pH, protein concentration, ionic strength, buffer, and temperature; optimum conditions are generally determined empirically via 1-D spectra. Solutions are usually buffered, at 10–50 mM, with phosphate or with deuterated buffer salts (e.g., Tris, acetate). Deuterated reducing agents, cation chelators, and proteolytic enzyme inhibitors may also be incorporated as necessary.

Obtaining NMR Data from Proteins and Assignment of NMR Resonances

Protein NMR spectra are usually recorded in aqueous solutions to obtain data from the exchangeable amide protons. In these spectra, the solvent water signal is at least 10^5 times more intense than the protein protons of interest and must be suppressed to allow detection of protein signals at an acceptable signal-to-noise ratio. The most common method for suppressing the water signal in multidimensional NMR uses pulsed-field gradients. Full discussion of solvent suppression techniques can be found in a separate article.

One-Dimensional NMR Data

Initial assessment of the suitability of a protein sample and preliminary solution optimization can be achieved via 1-D ^1H NMR experiments. Broad signals may indicate protein aggregation and suggest that further sample

Figure 2 One-dimensional 950 MHz ^1H NMR spectra of hen egg-white lysozyme (HEWL). The lower spectrum illustrates the range of proton chemical shifts observed in the well-dispersed spectrum of a folded, native protein. The positions of upfield-shifted methyl signals and downfield-shifted H^α and H^N signals are shown. The upper spectrum illustrates the lack of chemical shift dispersion observed in the spectrum of an unfolded or denatured protein. The random coil positions of H^N , aromatic, H^α , and methyl signals are shown.

optimization may be required. The presence (or absence) of protein structure can be assessed from the distribution of signals; methyl signals shifted upfield of ~ 0.5 ppm, downfield-shifted H^α signals (5–6 ppm), and $^1\text{H}^\text{N}$ signals shifted downfield of ~ 8.5 ppm indicate that a protein is ‘structured.’ For a denatured (or random coil) protein, such signals are absent from these regions. This is highlighted in a ^1H NMR spectrum of lysozyme in Figure 2.

Two-Dimensional Homonuclear NMR Data and Sequential Assignment

Having established optimum sample conditions, all subsequent assignment and structural data are obtained from multidimensional NMR experiments. NMR spectra of peptides and small proteins can be fully assigned in a systematic manner by a sequential assignment procedure using well-resolved two-dimensional (2-D) homonuclear spectra and a knowledge of the amino acid sequence of the protein. Assignment is carried out in a two-stage procedure. The spin systems of individual amino acids are first identified via ^1H – ^1H scalar couplings in COSY (correlation spectroscopy) and TOCSY (total correlation spectroscopy) experiments. Spin system identification is

facilitated by the fact that many amino acids, either individually or in groups, give rise to characteristic peak patterns in COSY and TOCSY spectra. In the second stage of assignment, the spin systems are connected to neighboring amino acids across the peptide linkage via ‘through-space’ correlations in NOESY (nuclear Overhauser effect spectroscopy) experiments. This procedure depends on the fact that for all of the sterically allowed values of the torsion angles ϕ , ψ , and χ_1 , short inter-proton distances ($< \sim 5$ Å), and therefore NOEs, will be observed between the H^N of residue i and at least one of the H^N , H^α , or H^β of residue $i-1$ (Figure 3). Once several spin systems have been identified as belonging to neighboring residues, a sequence-specific assignment can be made by comparing the spin system types of the adjacent residues with the amino acid sequence of the protein.

Multidimensional Heteronuclear NMR Data and Triple-Resonance Assignment

For larger proteins (>100 residues), 2-D ^1H NMR spectra become very crowded and overlap of signals hampers analysis. Full assignment can, in these cases, be achieved by spreading data into three or four dimensions

Figure 3 Schematic representation of the ^1H – ^1H NOEs used for sequential assignment of the NMR spectra of proteins. The arrows indicate the short distances ($< 5 \text{ \AA}$) between the H^{N} of residue i and the H^{N} , H^{α} , and H^{β} of residue $i - 1$.

to increase signal resolution and by further spectral simplification through ^{15}N and ^{13}C isotope editing. The heteronuclei (^{15}N or ^{13}C) can be correlated with their attached proton using 2-D heteronuclear single-quantum coherence (HSQC) experiments; these are sensitive experiments due to the large (~ 90 – 140 Hz) one-bond couplings between ^1H and ^{15}N or ^{13}C .

Labeling with ^{15}N alone can be sufficient to overcome spectral overlap for proteins of up to $\sim 20 \text{ kDa}$ and spectra of such proteins can be assigned using the sequential assignment methodology described earlier. Information on spin system types or sequential connectivities can be obtained by converting a 2-D ^1H TOCSY or NOESY experiment into a 3-D experiment by adding a ^1H – ^{15}N HSQC step. These 3-D experiments can be considered as a series of 2-D homonuclear experiments in which each is edited by a different ^{15}N frequency. Thus, having established amide ^1H – ^{15}N pairs via the HSQC, the TOCSY–HSQC correlates H^{α} and some side-chain protons to these pairs and residue types can be assigned. Sequential assignment can then follow in a manner analogous to the 2-D procedure (see the preceding section) via the NOESY–HSQC spectrum. Other 3-D experiments have been devised to facilitate assignments of ^{15}N -labeled proteins. One such, which is of particular use for identifying helical regions of a protein, is the HSQC–NOESY–HSQC experiment, which allows identification of ^1H – ^1H NOEs between residues with degenerate amide proton resonances.

For larger proteins ($> 20 \text{ kDa}$), double labeling with ^{15}N and ^{13}C is required and assignments are no longer based on ‘through-space,’ sequential NOEs. Instead, assignments are made via a range of 3-D triple-resonance experiments in which ‘through-bond’ sequential connectivities are established via magnetization transferred through ^{13}C – ^{13}C and ^{13}C – ^{15}N couplings; these experiments allow both intra- and interresidue connectivities to be identified. These couplings are usually at least as large as the ^{13}C line width for proteins of up to $\sim 30 \text{ kDa}$ and are reasonably independent of the protein backbone conformation. A summary of the magnitudes of coupling

Figure 4 Schematic representation of the peptide backbone, showing the magnitudes of the one-bond couplings constants, and the two-bond $\text{N}(i)$ – $\text{C}_{\alpha}(i - 1)$ coupling constant (---), that are utilized in multidimensional triple-resonance experiments used for assignment.

constants utilized in these triple-resonance experiments is shown in **Figure 4**. These experiments each focus on a particular coupling network (their nomenclature usually reflects this in a logical manner), and several different experiments may perform the same correlation, but via a different route. For example, the 3-D HNCO experiment correlates the $^1\text{H}^{\text{N}}$ and ^{15}N of residue i with the $^{13}\text{C}(\text{O})$ of residue $i - 1$ (**Figure 5**). Spin system information is obtained using experiments that detect $^{13}\text{C}^{\beta}$ chemical shifts, which vary according to amino acid type. For example, the CBCA(CO)NH experiment correlates $^{13}\text{C}^{\beta}$ and $^{13}\text{C}^{\alpha}$ of residue i with ^{15}N and $^1\text{H}^{\text{N}}$ of residue $i + 1$; magnetization transfer occurs via $^{13}\text{C}(\text{O})$ of residue i , but this chemical shift is not detected (**Figure 5**).

For proteins above $\sim 30 \text{ kDa}$, the T_2 of $^{13}\text{C}^{\alpha}$ becomes short and experiments such as HNCA, which correlates $^1\text{H}^{\text{N}}$ and ^{15}N of residue i with $^{13}\text{C}^{\alpha}$ of both residues i and $i - 1$, no longer work efficiently. This problem can be overcome by triple labeling with ^{15}N , ^{13}C , and ^2H . When the deuterated protein is dissolved in an H_2O buffer, the $^1\text{H}^{\text{N}}$ back-exchange into the sample, allowing their detection. Deuteration results in longer T_2 values for $^{13}\text{C}^{\alpha}$ and $^{13}\text{C}^{\beta}$ so that assignment can be carried out using triple-resonance experiments including HNCA, HNCO, and CBCA(CO)NH.

For larger proteins ($> \sim 40 \text{ kDa}$), T_2 relaxation times for ^{15}N , which are dominated by the attached $^1\text{H}^{\text{N}}$, become so short that the HSQC element of all triple-resonance experiments no longer works efficiently. In this case, the HSQC element can be replaced by transverse relaxation-optimized spectroscopy (TROSY). TROSY applies constructive use of interference between dipole–dipole and chemical shift anisotropy relaxation, resulting in a $^1\text{H}^{\text{N}}$ – ^{15}N correlation peak that is significantly sharper than that observed in HSQC. The TROSY effect is dependent on magnetic field and is predicted to be optimal at $\sim 1000 \text{ MHz}$. Combined with high levels of deuteration, 3-D TROSY-based triple-resonance experiments including TROSY–HNCA and TROSY–HNCO

Figure 5 Representation of the nuclei that are correlated in typical 3-D triple-resonance experiments: (a) HNCO, (b) HNCA, (c) HN(CO)CA, (d) HN(CA)CO, (e) CBCA(CO)NH, (f) CBCANH. Nuclei shown in bold are detected in the three dimensions of the experiments whereas nuclei shown in italics are used for magnetization transfer, but their chemical shifts are not measured.

can be used for assignment of the spectra of larger proteins.

Protein Structure Information from NMR Parameters

Conformation-dependent data, primarily in the form of NOEs, scalar coupling constants, and chemical shifts, are obtained from essentially the same experiments as the assignments. Additional structural information can also be extracted from residual dipolar couplings (RDCs) and amide exchange data. It should be emphasized here that all of these NMR parameters are population weighted and time averaged; thus, as molecular systems are inherently dynamic in nature, these parameters do not in general represent single, precise values of interatomic distances and angles. Nevertheless these NMR parameters, which are considered in the following text in terms of the structural information they represent, provide useful restraints to allow calculation of protein structures and, in the case of proteins that cannot be crystallized, access to structural information that cannot be obtained by other means.

Nuclear Overhauser Effects

A cross-peak in a NOESY experiment indicates dipolar cross-relaxation between two nuclei that are spatially close to one another. The cross-peak intensity is dependent on the inverse sixth power of the distance between the two nuclei. Thus, for two protons, i and j separated by a distance r , which give rise to a NOESY cross-peak, intensity of that cross-peak I is proportional

to r^{-6} . This simplified relationship assumes that the protein can be considered as a rotating rigid body in which correlations times for all proton pairs are the same, and are equal to the correlation time for the overall tumbling of the protein. For a more thorough analysis, account must be taken of, among other factors, internal mobility and spin diffusion. These are dealt with in greater detail in a separate article.

Interproton distances can, therefore, be determined from well-resolved, 2-D or 3-D NOESY data, by analysis of cross-peak intensities. These may be obtained by volume integration and can be converted into estimates of interproton distances for NOESY data at short mixing times. In this method, each proton pair is considered in isolation and NOESY cross-peak intensities are compared with a reference cross-peak from a proton pair of fixed distance, such as a geminal methylene proton pair or aromatic ring protons. A problem inherent to this approach is that the fixed distance is usually smaller than the unknown distance; this usually leads to systematic underestimation of the latter.

An alternative method of analysis of NOESY data is to measure the maximum peak amplitude or to count the number of contours in the 2D spectrum. NOESY cross-peaks can then be classified as strong, medium, or weak and can be translated into upper distance restraints of ~ 2.5 , 3.5 , and 5.0 Å, respectively. The lower distance constraint is usually the sum of the van der Waals radii (1.8 Å for protons). This simple approach is reasonably insensitive to the effects of spin diffusion or nonuniform correlation times and can usually lead to definition of the protein structure, provided a sufficiently large number of NOEs has been identified.

Coupling Constants

Geometric information, particularly for the bonds of the peptide backbone (**Figure 1**), can be obtained from vicinal spin–spin coupling constants. The magnitude of the coupling constant J is dependent on the dihedral angle θ as well as the nature and orientation of substituents as defined by the Karplus relationship, which has the general form:

$${}^3J = A \cos^2\theta - B \cos\theta + C$$

For a given coupling constant, there are up to four valid solutions of the Karplus equation although knowledge of protein torsion angles (from protein structure databases) can be used to discount unlikely values.

The ${}^3J_{\text{NH}\alpha\text{H}}$ coupling constant, which is dependent on the dihedral angle $[\text{HN}_i\text{--N}_i\text{--C}\alpha_i\text{--H}\alpha_i]$ ($\theta = \phi - 60^\circ$ for L-amino acids), is commonly used for assessing secondary structure. Thus, a sequence of small (< 5 Hz) values indicates an α -helix, whereas extended β -structure has large (> 9 Hz) values. Intermediate values are indicative of a nonstandard structure or, more commonly, conformational averaging. For unlabeled proteins, the ${}^3J_{\text{NH}\alpha\text{H}}$ values can be measured, in exceptional cases for small proteins, from high-digital-resolution 1-D spectra but are more commonly obtained from 2-D ${}^1\text{H}$ – ${}^1\text{H}$ COSY spectra. If ${}^{15}\text{N}$ -labeled protein is available, these coupling constants can be extracted from 2-D ${}^1\text{H}$ – ${}^{15}\text{N}$ HMQC (heteronuclear multiple-quantum coherence)- J or 3-D ${}^1\text{H}$ – ${}^1\text{H}$ – ${}^{15}\text{N}$ HNHA, which correlates ${}^3\text{H}^{\text{N}}$, ${}^1\text{H}^{\alpha}$ and ${}^{15}\text{N}$, spectra.

Chemical Shifts

The chemical shift of a resonance reflects the chemical environment of the atom that gives rise to it. This is determined mostly by covalent bonding and, to a smaller extent, by the nonbonded environment. In unstructured peptides, each amino acid exists in an ensemble of conformations, and the random coil chemical shift represents the population-weighted mean value of these environments. The chemical shifts for amino acids in denatured proteins are close to random coil values; however, for structured proteins, many resonances are far removed from their random coil position (**Figure 2**).

The availability of chemical shift assignments for many proteins of defined structure has allowed changes in chemical shift from random coil values to be related to secondary structure and, consequently, to be used predictively. Thus, upfield shifts of ~ 0.3 ppm are characteristic of ${}^1\text{H}^{\alpha}$ in α -helices, whereas ${}^1\text{H}^{\alpha}$ in β -sheets experience downfield shifts of ~ 0.3 ppm. Similar effects are observed for ${}^{13}\text{C}$ chemical shifts of ${}^{13}\text{C}^{\alpha}$, which are shifted downfield by ~ 3 ppm in α -helices and upfield by ~ 1.5 ppm in β -sheets. A sequence of similar chemical

shift changes can help in the initial characterization of regions of secondary structure. A more detailed analysis of ${}^{13}\text{C}^{\alpha}$, ${}^{13}\text{C}^{\beta}$, ${}^{13}\text{C}(\text{O})$, and ${}^1\text{H}^{\alpha}$ chemical shifts, in relation to a database of shifts from proteins of known structure, can be used to define ϕ and ψ torsion angles.

Residual Dipolar Couplings

Dipolar couplings between two magnetically active nuclei (${}^1\text{H}$, ${}^{13}\text{C}$, or ${}^{15}\text{N}$) are generally averaged to zero for proteins tumbling isotropically in solution. If the protein molecule can be induced to behave anisotropically then these couplings will not be averaged completely and ‘residual’ dipolar couplings (RDCs) can be measured. A variety of media exist that will induce partial alignment of proteins in solution; these include DMPC/DHPC (dimyristoylphosphatidylcholine/dihexanoylphosphatidylcholine), bicelles, phage particles, and strained polyacrylamide gels. RDCs depend on the distance between the two nuclei, the orientation of the internuclear vector with respect to an overall alignment tensor, and the magnitude of the alignment tensor components. RDCs are usually measured for directly bonded nuclei (${}^1\text{H}^{\text{N}}\text{--}{}^{15}\text{N}$, ${}^1\text{H}^{\alpha}\text{--}{}^{13}\text{C}^{\alpha}$, ${}^{15}\text{N}\text{--}{}^{13}\text{C}^{\alpha}$, ${}^{13}\text{C}^{\alpha}\text{--}{}^{13}\text{C}(\text{O})$) with a fixed internuclear distance. RDCs appear as an additional contribution to the splitting from scalar J coupling; the RDC (D) can be determined by taking the difference between the splitting measured under anisotropic conditions ($J + D$) and the splitting observed in isotropic solution (J). Because RDCs depend on the orientation of internuclear vectors with respect to a single alignment frame, they provide information about the relative orientations of a large number of directly bonded atomic pairs with respect to each other. Thus, RDCs can provide important structural information that is complementary to that obtained from NOEs, coupling constants, and chemical shifts.

Amide Proton Exchange and Hydrogen Bonds

Reduced rates of exchange of backbone amide protons with the bulk solvent water indicate reduced solvent accessibility and likely involvement in hydrogen bonds. Almost all amide protons in regions of regular protein secondary structure (except for those at the beginning of α -helices or at the edges of β -sheets) are hydrogen bonded. Measurement of amide proton exchange rates by following the time-course of the disappearance of signals in COSY, TOCSY, or HSQC spectra therefore provides supportive evidence of secondary structure. Amides with slow exchange rates can be assumed to be hydrogen bonded, but the identity of the hydrogen bond acceptor must be deduced from regular secondary structure patterns. In favorable cases, the ${}^1\text{H}^{\text{N}}$ and ${}^{13}\text{C}(\text{O})$ groups involved in a hydrogen bond can be identified directly

from peaks observed in a modified HNC α triple-resonance experiment.

Deriving Protein Structures from NMR Data

Extensive computational calculations are necessary to translate the information contained within NMR data into a protein structure. The quality of the structure obtained depends on the accuracy and, to a greater extent, quantity of the NMR data. Regions of protein secondary structure are identified via characteristic short-range (i.e., ≤ 5 residues apart) NOEs, H^N-H^Z coupling constants, chemical shifts, and amide proton exchange data. Longer-range NOEs and RDCs then define the tertiary structure, which can be refined further against all available data.

Calculation of protein structures from NMR data requires conversion of the NMR data into distances and angles, usually in the form of allowed ranges. NOEs and hydrogen bonds are converted into distance restraints whereas coupling constants and chemical shifts are converted into torsion angle restraints. These restraints are incorporated into protein structure calculations, such that deviation from these values incurs an energetic penalty. In these calculations, distances and angles within a protein structure are optimized using a combination of distance geometry, molecular dynamics, and simulated annealing procedures.

Distance geometry calculations aim to optimize all interatomic distances within a protein on the basis of the experimental restraints and are often used to define the global fold of a protein. This may then be refined using restrained molecular dynamics simulations in which structures evolve over time under the influence of a force field that contains potential energy terms for both covalent and nonbonded interactions and includes NMR restraints. A variation in molecular dynamics is simulated annealing, which differs in that normally 'prohibited' potential energy barriers can be crossed, allowing regions of a molecule to 'pass through' one another, thereby sampling larger regions of conformational space; this technique does not require a defined starting structure. After optimization of the NMR restraints by any or all of these techniques, the potential energy of the resulting structures is minimized by molecular mechanics calculations to determine the lowest-energy family of structures. The accuracy of the protein structure can be further increased by refinement against RDCs.

Structural calculations usually result in an ensemble of protein structures that must be assessed to determine how well they satisfy the initial restraints. Violations in excess of 1 Å may indicate that NOEs have not been correctly assigned. Comparison of calculated and experimental NOEs can also lead to an 'R factor' that gives an indication

of the quality of the structures in a manner analogous to that used in X-ray crystallography. The structure can be validated using NMR data, such as a set of RDCs or a subset of NOEs, which were not used as restraints in the original calculation. An alternative is to measure the root mean square deviation of the ensemble of structures from the average structure. This measure should be used with care as it may indicate a high level of precision in the structures but not give a true indication of their accuracy.

Other Applications of Protein NMR

Protein Dynamics

Static 3-D protein structures cannot always explain biological processes or point the way, for example, to rational drug design; the dynamic properties of a protein may be of equal functional importance. Internal motions within proteins were recognized by early NMR experiments, and NMR spectroscopy has developed into a powerful technique for the study of dynamics, from the picosecond motions of bond vectors to millisecond motions. For ^{15}N -labeled proteins, information about backbone dynamics and motions of nitrogen-containing side chains can be obtained via ^{15}N relaxation experiments. Relaxation of ^{15}N nuclei is usually dominated by dipole-dipole interactions with the directly bonded proton and this relaxation is dependent on internuclear distance (which is fixed) and the rotational correlation time, which is only uniform throughout a 'rigid' protein. Proteins, however, usually contain regions that have greater flexibility, such as surface loops, which have different local correlation times that are reflected in ^{15}N relaxation times. Recently, relaxation dispersion methods have been used to probe slower timescale (μs to ms) motions and to characterize 'invisible' states of proteins.

Protein Folding

A major advantage of NMR over X-ray crystallography is the ability to characterize the structure and dynamics of unfolded and partially folded states of proteins. These are of importance in protein folding and many cellular processes; indeed, many proteins or domains are intrinsically unstructured and only become structured on binding other molecules. In these states, proteins exhibit rapid fluctuations between a range of conformations and insight into these processes can be gained from NMR, through either studying equilibrium states or direct monitoring of kinetic folding events.

Concluding Remarks

There are other areas of protein NMR that have not been considered here but are covered elsewhere in the

encyclopedia. These include the binding of ligands and the study of membrane-associated proteins in detergent micelles or phospholipids bilayers using solid-state magic-angle spinning techniques.

This article has focused on structural aspects of protein NMR. Determination of a *de novo* protein structure by NMR takes longer, in general, than by X-ray crystallography – provided the protein can be crystallized. However, NMR is the only technique for obtaining high-resolution structural data from proteins that cannot be crystallized and for which appropriate concentrations of nonaggregated protein can be achieved. Limitations of molecular size can be overcome, as with other biochemical and structural techniques, by considering protein fragments, or domains. Structural data for large proteins can thus be obtained for domains individually and the linkage and assembly of domains can then be determined; RDCs can be useful in defining the relative orientations of domains whereas ^{15}N relaxation can identify if linkers are rigid or flexible.

To summarize, NMR spectroscopy can provide a wealth of structural information about proteins and, leading from this, a greater insight into protein interactions and dynamic processes.

Introduction

The ability to comprehensively and accurately measure biological molecules on a global scale in a high-throughput mode is a key to systems biology studies that has had, and will continue to have, profound impacts on biological research. However, unraveling the complexity of biological systems requires the integration of information from multiple 'omic' platforms (e.g., transcriptomics, proteomics, and metabolomics). Although the genome of an organism may be considered static, gene expression is a dynamic process that is constantly influenced by environmental and physiological conditions. Thus, for complex biological systems, a wealth of information can be gained by monitoring the actual gene products (i.e., mRNA and proteins) being expressed to maintain cellular function. Tracking transcript levels exclusively, although currently more sensitive, has limitations for understanding the mechanisms of biological processes. Recent detailed studies have shown that mRNA levels do not necessarily correlate well with protein abundance, presumably because different mRNAs exhibit different rates of translation and turnover. Furthermore, the amount of functional protein (as translated by the mRNA) may be essentially independent of mRNA levels altogether as a result of posttranslational modifications (PTMs), alternative splicing, or differential rates of protein turnover. Thus, measuring both mRNA and protein abundances provides more comprehensive information about the macromolecules most intimately involved in cellular regulation and operation. Proteomics is the global-scale characterization of proteins and their abundances in a biological system including the protein spatial distribution and temporal dynamics.

An essential component for establishing a comprehensive model of any biological system is the accurate identification and quantification of protein abundances at any given time. The challenges for proteomics include the identification of all the proteins expressed, under many different conditions (e.g., in health and disease), and the characterization of protein modifications, interactions, and structure. Such information can provide a basis for understanding genetic variants, gene functions, and the mechanisms of action needed to develop the means to diagnose, treat, and protect against disease. MS plays a crucial role in enabling the analysis of proteomes and is typically the method of choice for identifying proteins present in biological systems. Herein, several MS-based methodologies are introduced for proteome analysis currently in use.

Classical (Gel-Based Bottom-Up) Proteomics

In its infancy, proteomics research relied heavily on visualizing and identifying overall protein changes occurring in an organism, tissue, or cell type using two-dimensional electrophoresis (2DE). Differentially changed protein spots revealed relative proteome changes between samples. Further analysis of the protein spots using MS was one of the earliest means of characterizing an organism's proteome, and so henceforth, this strategy became known as 'classical proteomics.' With its high resolution (>10000 protein spots per gel) and ability to separate protein species stemming from PTMs, alternative splicing, or genetic variability, classical proteomics remains a widely used tool in proteomic analyses.

To perform classical proteomics, proteins taken from lysed cells are separated by 2DE. The first dimension of separation is usually based on isoelectric point (pI) employing a process known as isoelectric focusing (IEF) on a narrow gel strip composed of acrylamide with covalently linked ampholytes, which aid in maintaining a pH gradient when the proteins are placed in an electric field. Proteins display a net zero charge at their pI. Hence, in the presence of an electric field, if the protein is at a pH where it has either a net positive or a negative charge, it will migrate until it reaches its pI. After the IEF is complete, the strip is exposed to sodium dodecyl sulfate (SDS) and other denaturants to open up and coat the proteins with a net negative charge that is proportional to the protein's size. The pI strip is then placed on an SDS-polyacrylamide gel where another electric field is applied, forcing the negatively charged proteins to migrate through the gel, separating them based on molecular mass. After the second dimension of electrophoresis is completed, the proteins embedded in the polyacrylamide gel appear in the form of spots, which are visualized using one of several staining methods. The amount of each protein can be relatively quantified and compared across different gels by measuring the placement, density, and size of the spots. Differential in-gel electrophoresis (DIGE) is a more recently developed protocol that uses proteins covalently tagged with spectrally different fluorescent dyes to quantify gel spots.

2DE provides information regarding pI and approximate molecular mass of a protein but does not necessarily reveal the sequence or identity of the protein. To identify the proteins, usually an in-gel digestion is applied to

Figure 1 Flowchart delineating the different proteomic methods and the workflows associated with each. Such diagrams illustrate the key role of sample preparation and separation for the analysis of expressed proteins in biological systems. Ultimately, all methods rely on MS information for protein identification. The digestion of proteins into smaller peptides before MS analysis is the primary difference between bottom-up and top-down strategies.

spots of interest. This technique consists of spot excision, several washing steps, and incubation with a protease, which liberates peptides into the surrounding solution. The resulting peptide mixture is typically analyzed by matrix-assisted laser desorption/ionization (MALDI) MS or by liquid chromatography (LC) separations coupled with electrospray ionization (ESI) MS/MS. The peptide masses obtained in MALDI-MS analysis provide a fingerprint to confer protein identity from expected masses (calculated from known protein sequences and protease cleavage sites). In the case of LC-ESI-MS/MS analyses, one or several of the peptide ions are fragmented typically using collisionally induced dissociation (CID) to produce the key sequence-specific ions.

The classical proteomic approach provides good resolution at the protein level, allowing for the separation of isoforms and posttranslationally modified proteins from their nonmodified counterparts. Additionally, this type of proteomic analysis is most affordable and accessible, allowing most labs to perform it. However, these methodologies suffer from significant drawbacks associated with the separation method and staining procedures, such as the inability to analyze proteins with extreme pI or mass, a limited throughput despite significant automation efforts,

relatively large sample requirements (50–200 µg total protein per analysis), inadequate detection limits (0.1–10 ng protein per spot), and narrow dynamic range ($<10^3$). With the advent of more sophisticated instrumentation, techniques, and bioinformatics tools, larger-scale and higher-throughput proteomics strategies are now widely accessible. These newer solution-based (i.e., gel-free) proteomics techniques are primarily categorized as either bottom-up (e.g., shotgun) or top-down proteomics (**Figure 1**).

Shotgun Proteomics

In recent years, there has been an intensification of efforts to develop ‘gel-free’ approaches that employ alternative separation methodologies combined with MS to address the limitations of 2DE. Analysis of the protein digests from whole cells or cell fractions without prior separation of the mixture into individual proteins is common to all of the ‘gel-free’ approaches. Gel-free techniques became feasible in the late 1990s due to the advances in all aspects of proteomics: technical advances in micro- and nano-format separation techniques, mass spectrometers, and bioinformatics and an enormous

increase in available genomic data. A variety of mass analyzers, each having its own specific application niche, has been employed in proteomics, including ion traps, time-of-flight (TOF) analyzers, triple-quadrupoles (QqQ), and various hybrids, such as TOF–TOF, q-TOF, and ion traps coupled with Fourier transform ion cyclotron resonance (FTICR) or Orbitrap mass spectrometers. Powerful separations before MS analysis typically enable detection of a large number of peptides and, through the search of the appropriate database (e.g., using Sequest or Mascot), allow the identification of a significant percentage of the predicted proteome.

In 1999, Yates et al. proposed a 2D chromatography strategy known as multidimensional protein identification technology (MUDPIT), which revolutionized the concept of high-throughput proteomics. The premise behind MUDPIT in particular and shotgun proteomics in general is that all proteins undergo proteolytic digestion, which converts the large less-soluble proteins into manageable polypeptides that can be separated and analyzed by LC-MS. By focusing on the separation and identification of peptides rather than proteins, some of the challenges associated with the analysis of intact proteins (e.g., hydrophobic or high molecular mass proteins) can be avoided or mitigated. Throughput is increased due to the use of liquid-based separations instead of the more time- and sample-consuming gels.

A typical shotgun proteomic workflow (**Figure 2**) begins when the proteome is first digested into peptides using a protease with known cleavage specificity. The most common protease used is trypsin, which catalyzes a hydrolysis reaction that cleaves proteins at the carboxyl side of arginine and lysine. The resulting peptides are then separated by a combination of chromatography steps and then analyzed by extensive ESI-MS/MS analyses (typically with an ion trap mass spectrometer) to produce many tandem spectra (MS/MS) using CID, which produces sequence-specific b- and y-ion patterns. Using a combination of peptide chromatography strategies, such as MUDPIT (strong cation exchange (SCX) followed by reverse phase (RP) chromatography), a greater peak capacity and a substantial reduction in sample complexity are achievable. This enables a greater number of less abundant proteins to be identified, which is significant as these less abundant proteins often have biologically significant roles.

Although fully automated SCX-RP-LC systems exist, the combination is difficult to optimize because the first dimension produces fractions resulting from distinct stepwise increases in salt concentration, and this in turn hinders optimal separation peak capacity. As a compromise between high sensitivity, high peak capacities, ease of use, and throughput, many groups have chosen off-line versions of this method, which allows for optimization of two separation dimensions independently.

Although bottom-up shotgun proteomics methods are capable of providing identification and quantitation of a vast number of proteins in a high-throughput manner, many challenges still exist. Currently, there are many different peptide assignment algorithms (e.g., SEQUEST, Mascot, and X! Tandem), and they all use slightly different approaches to identify which peptides are present. In addition, peptide assignments will depend on the filters and criteria used during data processing. Researchers therefore rely on several techniques including reversed and scrambled database searches and probability algorithms (e.g., PeptideProphet) to determine false discovery rates (FDR). Finally, because changes at the protein level (i.e., presence of isoforms, PTMs) are more difficult to determine after tryptic digestion, some biologically relevant information is ultimately unavailable using bottom-up approaches.

Accurate Mass and Time Tag Proteomics

Bottom-up shotgun proteomics provides a sequence identification from the MS/MS data and a predictable elution time for each identified peptide. The normalized elution time and exact parent peptide mass calculated from the peptide sequence can be used as a reference to make peptide assignments in additional LC-MS analysis without fractionation or MS/MS analyses. This is the basis of the so-called accurate mass and time (AMT) tag approach to proteomics. The accuracy of peptide assignments is determined by the precision and accuracy of the measured parent ion mass and normalized elution time (NET). For these reasons, typically FTMS (meaning FTICR or Orbitrap mass spectrometers) instruments are used in the latter LC-MS analyses along with significant efforts to align multiple LC-MS analyses. Substituting routine LC-MS/MS analyses (shotgun approach) with LC-FTMS analyses (AMT tag approach) significantly increases overall throughput and sensitivity. Additionally, quantitative intensity information related to the protein's abundance can be discerned from these analyses. The AMT tag approach often generates very large and complex data sets requiring additional computational power and expertise. Despite the challenges, many tools are currently available to aid in the process of mass tag database development, deisotoping (neutral mass calculation), peak matching (between experimental LC-MS features and AMT tags), data normalization, and visualization.

Quantitation

The earliest attempts at quantifying proteome changes were based on spot comparisons between 2DE gels, immunoblots, and ELISA assays. As proteomic strategies

Figure 2 Typical workflows of a shotgun proteomics experiment and an accurate mass and time (AMT) tag proteomics experiment. Note that in the AMT approach, the initial fractionation and LC-MS/MS analysis (Stage 1) is performed only once. Subsequent LC-MS analyses of the biological system with high-resolution MS (Stage 2) are performed without fractionation. This provides a significant improvement in sample throughput and overall sensitivity when the analysis of multiple samples from a biological system is required, which is a common occurrence.

evolve from gel-based methods into liquid only-based methods, more reliance on quantitation using the MS peak intensities has emerged as the preferential means of quantitation with the use of immunoblots and ELISA assays as verification of observations.

There are two main approaches to quantitative measurement using MS (**Figure 3**): absolute quantitation, where the goal is to measure the actual concentration of the protein/peptide in the sample, and the more common relative quantitation, where the relative protein/peptide concentration is compared between two or more samples. Absolute quantitation is preferred when the peptides or proteins of interest are few and known, that is, biomarker validation. In the case of relative quantitation, the goal is to

study the global proteome response between biological states, that is, the proteome differences between a control proteome and one treated with a specific drug to determine the effects of the drug on the biological system.

MS as applied to proteomics is not an inherently quantitative analytical tool because the differences in the peptide ionization efficiencies, the total number of peptides being eluted into the mass spectrometer at a given time, and varying peptide conformations make all peptides (even those from the same protein) generate different instrument responses. For this reason, using MS peak intensities to quantify relative protein/peptide abundances (i.e., label-free quantitation) as well as translating peptide ion current values into protein abundance values (protein

Figure 3 Schematic diagram showing the differences between relative and absolute quantitation strategies in proteomics. Labeling for relative quantitation between two (or more) samples can be performed on one of the initial samples (labeled sample shown green), typically whole cells (metabolic labeling), extracted protein (chemical labeling, labeled proteins shown green), or peptide level (chemical or enzymatic labeling, labeled peptides shown green) before sample mixing for analysis. By analyzing the labeled and unlabeled samples at the same time, the relative amount of protein between samples can be determined. Such analysis is useful for identifying protein abundance differences between biological states. In absolute quantitation, a known amount of labeled standard peptide (shown purple) is added to the sample before analysis. Using this method the absolute concentration of protein in the sample can be determined. Such measurements are ideal for determining biologically significant cellular protein concentrations.

roll-up) can be a challenge. Various stable isotope-labeling approaches have been introduced to compensate for these effects. These approaches involve the mixing (at the whole cell, protein, or peptide level) and simultaneous analysis of two samples distinctively labeled by stable isotopes that can be sufficiently resolved by MS. Peptides with the same sequence but with a different ratio of isotopes induce the same response in the MS detector. Hence, the changes in relative protein abundances are precisely reflected by the ratio of two isotopically different and resolvable versions of each peptide.

Stable Isotope Labeling

There are several ways to introduce stable isotopes into proteome samples, the simplest being to chemically synthesize the stable isotope-labeled peptides. This strategy facilitates absolute quantitation, but is practical only when studying few peptides, for example, a specific and small set of biomarkers. Known quantities of the isotopically labeled peptides spiked into the sample act as internal standards for determination of the quantity of the nonlabeled counterpart.

For global quantitative proteomic studies, the isotopes (typically ^2H , ^{13}C , ^{15}N , and ^{18}O) are introduced metabolically (e.g., using ^{15}N -enriched media or stable isotope-labeled amino acids in cell culture (SILAC)), chemically (e.g., tagging of cysteine residues using isotope-coded affinity tags (ICAT) or specifically reacting amines with iTRAQ (isobaric tags for relative and absolute quantitation) reagents for multiplexed experiments), or enzymatically (e.g., a trypsin-catalyzed transfer of ^{18}O from water to the C-terminus of peptides).

Although stable isotope incorporation has proven to be a robust means of comparing proteomes, there are still challenges involved with complete label incorporation into selected samples. Additionally, stable isotope-labeled chemicals and kits can be relatively expensive, and oftentimes few samples can be simultaneously compared. Since a labeled pair is required to make quantitative measurement, this approach is ineffective in detecting relatively large abundance changes (e.g., when peptide detection is exclusive for one group of samples). To address these challenges, the stable isotope-labeling approaches are complemented by the label-free approach that provides greater flexibility for comparative analyses.

Label-Free Quantitation

After greater adoption of shotgun proteomic methodologies, one of the first means of crude semiquantitative measurements was to count the number of peptides observed from each protein in each sample analysis. Although there was a loose correlation between the number of peptides identified and the quantity of corresponding

protein in the sample, this method was never shown to be robust and is often biased toward measuring changes only in a subset of large proteins, which are typically digested into many peptides. Hence, peptide counts gave way to spectral counting (also known as quantitative MUDPIT). Spectral counting estimates a protein abundance based on the total number (i.e., including all SCX-RP fractions) of MS/MS spectra yielding peptide identifications for that particular protein. The resulting protein abundances are typically normalized to the protein abundance across all biological samples. This normalization enables the relative protein abundance change to be determined for any particular biological sample, i.e. which proteins had increased or decreased expression for a particular biological state.

Within the AMT tag approach (Figure 2), normalized LC-MS peak intensities for the detected peptides are used to estimate the relative abundances of proteins in the complex mixtures and to compare relative abundances between similar samples. Although MS intensity-based quantitation is still not as accurate as stable isotope-labeling approaches, this method has the advantage of simpler sample preparation and is better suited for detection of relatively large abundance changes.

Ion accounting (proteome-wide absolute peptide quantitation) is also a burgeoning label-free method whereby an absolute protein quantitation for each protein is determined based on the average instrument response of the most abundant peptides observed for each protein relative to a known quantity of spiked-in standard (e.g., a trypsin-digested yeast alcohol dehydrogenase). This label-free method facilitates whole proteome comparisons between columns, different sample loading concentrations, different mass spectrometers, and even different proteome facilities.

Although all quantitation strategies have their strengths and weaknesses, an appropriate selection of a quantitation method based on cost, instrumentation availability, and the specific biological question needing to be answered can maximize the applicability and accuracy of the obtained proteomic results.

From a data analysis standpoint, peptide-centric measurements significantly complicate protein quantitation due to the existence of multiple protein isoforms. For instance, PTMs can significantly affect protein activity without a change in the overall protein abundance. As protein quantity is typically compiled using information obtained for multiple peptides in bottom-up approaches, the assumption of 'all peptides being equal' can potentially introduce significant errors since it is virtually impossible to know whether a peptide is specific to a protein isoform or common to multiple isoforms. For these reasons, measurements at the intact protein level provide an important adjunct to peptide-level measurements.

Proteomics of Intact Proteins (Top-Down)

Proteins in biological systems exist in a variety of protein isoforms (**Figure 4**) – proteins with a similar primary structure, but differing in PTMs, modified amino acid sequence (such as single-nucleotide polymorphisms), conformation, or processing/degradation state. Many of these modifications affect the protein activity, localization, and cellular function. Ultimately, the impact of these modifications is that a single gene results in many functionally distinct protein isoforms, which are dynamic in nature and change in response to the state of the biological system. Top-down proteomics inherently measures the differences in protein isoforms as PTMs result in a change in the mass of the intact protein and provides a unique opportunity to characterize the protein isoforms present in a biological system (**Figure 4**).

Significant progress has been made, and efforts continue to extend the capabilities of proteomics for the analysis of protein regulation through modification events, such as phosphorylation, that are key to understanding cellular signaling and response to environmental

stimuli. Hundreds of PTMs have been identified, and books have been written describing the effects of these modifications in biological systems. Perhaps more accessible to those who characterize PTMs using MS are internet databases that describe identified modifications in terms of potentially affected amino acids and characteristic observed mass shift of the modification. Typically, such databases include not only PTMs that occur in the biological system, but also potential chemical modifications of amino acids that can occur during sample preparation and analysis. Some of these chemical modifications are intentional for specific purposes of the analysis, such as adding labeling groups to specific amino acids to aid in protein quantification.

Top-down proteomics holds great potential for the complete characterization of protein isoforms (**Figure 4**). However, the identification of the protein and characterization of isoforms are complicated by the additional parameter space required for database searching, due to the high number of dynamic modifications required to correctly identify the protein isoforms. Indeed, proteomics began with the top-down methodology, but the

Figure 4 Initial processing results of mass spectra from intact protein LC-MS analysis of extracted histone proteins. The neutral molecular mass (M_r) of observed proteins has been calculated using isotopically resolved data. A bird's-eye view clearly illustrates the distribution of protein isoforms arising from amino acid substitutions and PTMs, such as acetylation (Ac) and methylation (M). Subsequent top-down analyses (i.e., intact protein MS/MS) can be performed in a targeted fashion to confirm and localize specific modifications or interesting proteins (e.g., proteins showing statistically significant change in abundance between two biological states).

bottom-up methodology currently provides significantly more protein identifications. It might seem counter-intuitive that chopping a protein into pieces and then identifying the pieces leads to more identifications than simply measuring the intact protein. This is due to the number of protein isoforms (**Figure 4**) and the increasing difficulty of obtaining useful MS/MS to aid in identification as the protein size increases. In addition, detection of proteins becomes more challenging as protein size increases due to protein signal being partitioned into more charge states (ESI), increased number of isoforms, larger isotope distributions, and so on. Similarly, effective separation of minute amounts of a complex mixture of proteins with a variety of physicochemical properties before MS analysis represents an overarching technical challenge.

Over the past few years, significant progress has been made to address these challenges, in terms of improved instrumentation and the development of novel dissociation methods. MS/MS strategies that involve gas-phase dissociation of intact proteins have demonstrated 100% protein sequence coverage and allowed for the complete characterization of protein isoforms (**Figure 4**), proteolytic processing events, and PTMs. The most recent and significant advancements in this context are electron capture dissociation (ECD) and electron transfer dissociation (ETD), which typically provide more uniform dissociation than conventional CID, while preserving the labile modifications.

The analysis of intact proteins in complex biological systems greatly benefits from the use of mass spectrometers with the highest achievable resolution and mass measurement accuracy. Naturally, FTICR MS plays a significant role in top-down proteomics due to the superior resolution and accuracy. Recent developments of other FTMS instrumentation (i.e., Orbitrap) and improved performance of MS in general have led to top-down analysis on other MS instrumentation as well. Developments such as these and the continued interest in characterizing the protein complement of biological systems, including PTMs, have led to great interest in applying top-down proteomics to systems biology applications.

Current top-down proteomics efforts have demonstrated the ability to identify hundreds of proteins in biological systems. Incorrect gene annotations and single-nucleotide polymorphisms have been identified and characterized by top-down proteomics. Despite these successes, the overall sensitivity is still somewhat less than with other methodologies. One strategy to improve the detection of posttranslationally modified proteins is to selectively enrich the sample for proteins containing target PTMs. Several methods for PTM enrichment have been developed including affinity chromatography, which can be incorporated into proteomic analysis workflows.

Popular affinity LC enrichment strategies include systems based on antibodies as well as immobilized metal affinity columns (IMAC), widely popular in the analysis of the phosphoproteome. Enrichment strategies can also be implemented for bottom-up proteomics, including enhanced detection of PTMs using differing enzymatic cleavages in multiple bottom-up analysis or through selective enrichment of peptides containing PTMs. Although increasing the number of identified peptides with PTMs, such enrichment strategies are still limited by the inability to characterize correlations between specific PTMs and the relationships between protein isoforms. These limitations can, in part, be addressed by the analysis of significantly larger enzymatic peptides (middle-down proteomics). These larger peptides are still readily analyzable on a variety of MS instrumentation platforms and typically result in increased protein coverage.

Ultimately, the only method, in general, to detect proteins with 100% sequence coverage is top-down proteomics. Current state-of-the-art techniques for the analysis of protein isoforms combine top-down and bottom-up techniques to leverage the strengths of each technique. In such hybrid strategies, top-down proteomics is used to characterize the protein isoforms using protein identification constraints obtained from bottom-up proteomics. Such constraints greatly simplify the identification of the intact protein isoforms and PTMs. MS/MS can be performed at the intact and peptide levels to further characterize protein isoforms.

Symbols

$\text{BG}_T(\text{M})$	gas-phase basicity of species M at temperature T
C_p	molar heat capacity at constant pressure
k	reaction rate constant
K_{eq}	equilibrium constant
$\text{PA}_T(\text{M})$	proton affinity of species M at temperature T
$S_T^0(\text{M})$	absolute entropy of species M at temperature T
T	temperature
$\Delta G_T^0(\text{eqn}[n])$	Gibbs free energy change on reaction
$\Delta H_T^0(\text{eqn}[n])$	enthalpy change on reaction at temperature T
$\Delta_f H^0(\text{M})$	enthalpy of formation of species M at temperature T
$\Delta S_T^0(\text{eqn}[n])$	entropy change on reaction
$\Delta S_{p,T}(\text{M})$	entropy of protonation of species M at temperature T
σ	rotational symmetry number

What is a Proton Affinity?

The ‘proton affinity’ and the related quantity ‘gas-phase basicity’ are defined as thermodynamic quantities that enable us to assign numeric values to the tendency of a molecule to accept a proton in the gas phase, or conversely, the tendency of a positive ion to donate a proton. That is ‘proton affinities’ and ‘gas-phase basicities’ provide quantitative measures of the acid–base properties of positive ions and the corresponding conjugate-base neutral species in the gas phase. These quantities have proved to be of scientific interest because of what they tell us about acid–base chemistry in the absence of a solvent, and of practical interest because of the applications of gas-phase proton transfer reactions in the analytical technique of chemical ionization mass spectrometry. This article will be concerned with defining these quantities, describing how they are determined experimentally, and discussing the status of the collective database of proton affinity/gas-phase basicity data. For a discussion of the implications of those data in organic

chemistry, the reader is referred to the available reviews of that subject, particularly to the work of R. W. Taft.

The proton affinity of species M, $\text{PA}_T(\text{M})$, is defined as the negative of the enthalpy change, ΔH_T^0 of the hypothetical gas-phase reaction at temperature T :

$$\begin{aligned} \text{PA}_T(\text{M}) &\equiv -\Delta H_T^0 \text{ (eqn [1])} \\ &= \Delta_f H_T^0(\text{M}) + \Delta_f H_T^0(\text{H}^+) - \Delta_f H_T^0(\text{MH}^+) \quad [2] \end{aligned}$$

while the gas-phase basicity, $\text{GB}_T(\text{M})$, is the negative of the Gibbs free energy change of the same reaction, ΔG_T^0 , and therefore related to the proton affinity through the standard thermochemical expression:

$$\begin{aligned} \text{GB}_T(\text{M}) &\equiv -\Delta G_T^0 \text{ (eqn [1])} \\ &= \text{PA}_T(\text{M}) + T\Delta S_T^0 \text{ (eqn [1])} \quad [3] \end{aligned}$$

The entropy change of eqn [1], ΔS_T^0 , can be expressed in terms of absolute entropies of the species involved:

$$\begin{aligned} \Delta S_T^0(\text{eqn [1]}) &= S_T^0(\text{MH}^+) - S_T^0(\text{M}) - S_T^0(\text{H}^+) \quad [4] \end{aligned}$$

$$= \Delta S_{p,T}(\text{M}) - S_T^0(\text{H}^+) \quad [5]$$

where $\Delta S_{p,T}(\text{M})$ is the entropy of protonation of M:

$$\Delta S_{p,T}(\text{M}) = S_T^0(\text{MH}^+) - S_T^0(\text{M}) \quad [6]$$

Thus, the relationship between the gas-phase basicity, proton affinity and entropy of protonation is given by

$$\text{GB}_T(\text{M}) = \text{PA}_T(\text{M}) + T[\Delta S_{p,T}(\text{M}) - S_T^0(\text{H}^+)] \quad [7]$$

In practice, proton affinity and gas-phase basicity values are used to predict the occurrence of bimolecular proton transfer reactions in the gas phase:

(In the text that follows, all references to compounds in reactions or in thermochemical equations refer to species in the gas phase, although a specific designator, (g), is omitted in the interest of improving readability.) At any particular temperature, the species, MH^+ or BH^+ , with the lower gas-phase basicity will transfer a proton to the conjugate base of the other (B or M), and the exact

difference in the gas-phase basicities can be measured by determining the equilibrium constant, K_{eq} , of eqn [8].

$$K_{\text{eq}} = \frac{[\text{BH}^+][\text{M}]}{[\text{MH}^+][\text{B}]} \quad [9]$$

$$\begin{aligned} -RT \ln K_{\text{eq}} &= \Delta G_T^0 \text{ (eqn [8])} \\ &= \Delta H_T^0 \text{ (eqn [8])} \\ &\quad - T\Delta S_T^0 \text{ (eqn [8])} \\ &= \text{GB}_T(\text{M}) - \text{GB}_T(\text{B}) \end{aligned} \quad [10]$$

Similarly, the enthalpy change of eqn [8] is equal to the difference in the proton affinities of the two species,

$$\Delta H_T^0 \text{ (eqn [8])} = \text{PA}_T(\text{M}) - \text{PA}_T(\text{B}) \quad [11]$$

and the entropy change is

$$\Delta S_T^0 \text{ (eqn [8])} = \Delta S_{\text{p},T}^0(\text{B}) - \Delta S_{\text{p},T}^0(\text{M}) \quad [12]$$

Although the occurrence or nonoccurrence of the proton transfer depends, at any given temperature, on the relative gas-phase basicity values, rather than the proton affinities, entropy changes associated with eqn [8] are typically (although not always) small, and proton affinities are, in practice, often consulted to predict the occurrence or nonoccurrence of particular proton transfer reactions.

According to common usage, unless it is stated otherwise proton affinity values are assumed to refer to 298 K, unlike electron affinities and ionization energies, which are specifically referred to 0 K. Therefore, it is useful to question how absolute values of proton affinities and protonation entropies vary with temperature. Differentiating and integrating eqn [2] with respect to temperature gives:

$$\begin{aligned} \text{PA}_{T_2}(\text{M}) - \text{PA}_{T_1}(\text{M}) \\ = \int [C_p(\text{H}^+) + C_p(\text{M}) - C_p(\text{MH}^+)] dT \end{aligned} \quad [13]$$

where the C_p are the molar heat capacities at constant pressure of the parenthetically indicated species, and the integration is carried out from T_1 to T_2 . At room temperature and above, $C_p(\text{H}^+)$ is taken as the classical value of $(5/2)R$, while $C_p(\text{MH}^+)$ will be close to, but greater than, $C_p(\text{M})$. Thus, for example, the difference in the value of the absolute proton affinity of M at 298 K and 600 K will be less than $(5/2)R$ ($600 \text{ K} - 298 \text{ K}$) = 6.2 kJ mol^{-1} .

The relative proton affinities, $\text{PA}_T(\text{M}) - \text{PA}_T(\text{B})$, of a pair of molecules, M and B in eqn [8], are essentially temperature independent, i.e.

$$\begin{aligned} -\Delta H_{T_1}^0 \text{ (eqn [8])} &= \text{PA}_{T_1}(\text{M}) - \text{PA}_{T_1}(\text{B}) \\ \approx -\Delta H_{T_2}^0 \text{ (eqn [8])} &= \text{PA}_{T_2}(\text{M}) - \text{PA}_{T_2}(\text{B}) \end{aligned} \quad [14]$$

This can be shown more formally by differentiating and integrating eqn [11] with respect to temperature,

$$\begin{aligned} &[\text{PA}_{T_2}(\text{M}) - \text{PA}_{T_1}(\text{B})] - [\text{PA}_{T_1}(\text{M}) - \text{PA}_{T_1}(\text{B})] \\ &= \int [C_p(\text{BH}^+) + C_p(\text{M}) - C_p(\text{MH}^+) - C_p(\text{B})] dT \end{aligned} \quad [15]$$

and noting that, because of the structural similarities of reactants and products, the heat capacity terms of eqn [15] will essentially cancel. When a relative proton affinity is derived from a van't Hoff analysis of a proton transfer equilibrium over a suitable temperature range, it is safe to assume that ΔH_T^0 (eqn [8]) is independent of temperature over that range. The above discussion suggests that the temperature independence of ΔH_T^0 (eqn [8]) can be safely assumed throughout the range $298 \text{ K} \leq T \leq 600 \text{ K}$. The feature is a generally observed phenomenon for reactions in which the number of reactants and products is the same, as is the case for proton transfer reactions. Similar considerations also apply to relative protonation entropies, i.e.

$$\begin{aligned} \Delta S_{T_1}^0 \text{ (eqn [8])} &= \Delta S_{\text{p},T_1}(\text{M}) - \Delta S_{\text{p},T_1}(\text{B}) \\ \approx \Delta S_{T_2}^0 \text{ (eqn [8])} &= \Delta S_{T_2}(\text{M}) - \Delta S_{T_2}(\text{B}) \end{aligned} \quad [16]$$

These considerations are important in establishing the validity of comparing data obtained at different temperatures, as must be done in evaluating gas-phase basicity and proton affinity data obtained under different experimental conditions.

How are Proton Affinities and Gas Phase Basicities Determined?

The proton affinity of any species can easily be derived from eqn [2], provided that enthalpies of formation of all the relevant species, M, H^+ and MH^+ , are known. Actually, in practice, there are relatively few species for which this condition is fulfilled. Usually, reliable data on the enthalpy of formation of MH^+ are lacking, since direct determination of this quantity requires either that the neutral precursor, MH, exists and is sufficiently stable that its ionization energy can be experimentally determined, or that the appearance energy of MH^+ formed in the dissociation of a larger molecule, MNH, can be determined:

Obviously, neutral analogues (MH) exist for only a very few protonated molecular species (MH^+). For example, although CH_5^+ (protonated methane) is a commonly used proton-donor species, the proton affinity of methane cannot be derived using this approach (eqn [2]), since the molecule CH_5 does not exist as a stable species,

nor is CH_5^+ formed as a fragment ion from any known dissociation of an organic molecular ion.

Most of the existing quantitative data on proton affinities and gas-phase basicities have been derived from determinations of equilibrium constants for proton transfer reactions (eqn [8]) in the gas phase (eqns [9] and [10]). Note that the measurement of a series of equilibrium constants at a single temperature will generate relative, rather than absolute, values for gas-phase basicities. In order to determine the enthalpy change of eqn [8] – that is, the relative proton affinities of M and B (see eqn [11]) – values for the entropy changes of the reaction must be obtained, through measurements of the equilibrium constant as a function of temperature (van't Hoff plot), through statistical-mechanical estimations or by *ab initio* calculations. Absolute values must then be assigned to the relative proton affinity scales using data for molecules whose position in the scale has been established, and for which absolute values of enthalpies of formation of both M and MH^+ are known from other measurements (eqn [2]).

Equilibrium constants for gas-phase proton transfer reactions can be determined as follows. A mixture, of known composition, of gases M and B is introduced into a mass spectrometric instrument designed to allow multiple collisions of ions before sampling (that is, designed so that ion–molecule reactions can be observed). Most such measurements have been carried out using one of three types of mass spectrometer that operate in very different pressure regimes. An ion cyclotron resonance (ICR) spectrometer typically observes such equilibria at very low pressures ($\sim 10^{-4}$ Pa), but at long times, so that there have been a sufficient number of collisions that an equilibrium can be established. Other measurements are done at higher pressures (100–1000 Pa) using a high-pressure mass spectrometer or a flow tube apparatus such as a flowing afterglow instrument.

If one or both of the parent molecular ions, M^{*+} or B^{*+} , is a species that contains a labile proton that can be transferred to M or B, then eqn [8] may be observed in the system. When neither M^{*+} nor B^{*+} serves as a source of protons, the proton transfer reaction (eqn [8]) may be initiated by the addition of a bath gas of some compound (methane, for example) that generates ions that transfer protons to the two subject compounds. If the reverse (endothermic) proton transfer reaction is fast enough to be observed on the timescale of the particular experiment, it is possible that a thermodynamic equilibrium can be established, and the equilibrium constant determined simply by observing the equilibrium ratio of the ion concentrations, $[\text{MH}^+]$ and $[\text{BH}^+]$; the composition of the mixture $[\text{M}]/[\text{B}]$ does not change, since the neutral compounds are present in great abundance relative to the ions. Each measurement provides a value for the Gibbs free energy change of eqn [8] at a single

temperature – that is, a value for the difference in gas basicities of molecules M and B (see eqn [10]). There exist large interlocking scales of relative gas-phase basicities (at a single temperature) determined by carrying out such measurements on series of molecules.

In certain cases, it is not possible to establish a proton transfer equilibrium, for example, if the subject compound, M, is unstable, or if MH^+ undergoes a fast reaction with M, or a reaction other than proton transfer with B. In these instances, other strategies have been adopted to determine relative gas-phase basicities or proton affinities. The simplest such approach is called the 'bracketing technique'; the ion MH^+ is generated and the occurrence or nonoccurrence of proton transfer with a series of molecules, B_1 , B_2 , etc., is observed. Reference compounds are chosen whose position in the relative scale of gas basicities is known.

Under the assumption that proton transfer will be observed only if the reaction is associated with a negative value of the Gibbs free energy, the basicity of M is taken to be between the basicities of B_1 and B_2 . In a variation of this approach proposed by Bouchoux, Salpin and Leblanc, called the 'thermokinetic method', trends in the reaction efficiency ($k_{\text{Rn}}/k_{\text{Collision}}$) with reactants of varying gas basicity are examined, and a correlation is used to predict the relative gas basicity.

Another approach, proposed by McLuckey, Cameron and Cooks, that is often used when compounds M and B are of low volatility is based on the observation of the collision-induced dissociation of proton-bound dimer ions, $\text{M} \cdot \text{H}^+ \cdot \text{B}$, formed in association reactions:

A semiquantitative relationship between the ratios of the two product ions and the relative proton affinities has been developed, and can be used to derive relative values of the proton affinities provided that the entropy changes associated with processes [20a] and [20b] are similar.

Quantitative information about relative proton affinities can also be obtained through the determination of the energy barrier associated with endothermic proton transfer reactions through an Arrhenius treatment of the temperature dependence of the rate coefficients, although this approach has rarely been used. In addition, determinations of the equilibrium constants of association reactions

can provide values for enthalpies of formation of the product ion, ABH^+ , provided the enthalpies of formation of AH^+ and B are known; if the enthalpy of formation of AB is also known, its proton affinity can be derived.

The 1998 Scale of Gas-Phase Basicities and Proton Affinities

Beginning in 1971, when the first determinations of gas-phase proton transfer equilibria were published, several extensive scales of relative gas-phase basicities were generated in different laboratories. With the exception of a small number of entropy-change measurements made in the laboratory of Paul Kebarle at the University of Alberta, most of these initial studies were carried out at a single temperature; in most cases, entropy changes were estimated from statistical-mechanical considerations, usually making the simplifying assumption that the complete expression derived from the partition functions could be adequately approximated using the ratio of the rotational symmetry numbers (σ) of M and MH^+ :

$$\Delta S_p^0(M) = R \ln[\sigma(M)/\sigma(MH^+)] \quad [22]$$

Using such estimated entropy changes, the experimentally determined interlocking scales of relative basicities were converted to scales of proton affinities. By the early 1980s, values of proton affinities for about 800 molecules had been reported, but comparing data from different laboratories was not always straightforward because different researchers chose different primary standards to assign absolute values to the proton affinities, and proton affinity values assigned to these reference standards were not always internally consistent. Therefore, in 1984 the Ion Energetics Data Center at the National Bureau of Standards (now the National Institute of Standards and Technology) carried out a comprehensive evaluation of available data to put all data on the same basis, and provide an internally consistent scale.

That evaluated scale (sometimes referred to as 'the NBS scale') proved to be sufficiently useful that it continues to be cited years after its publication. However, in the intervening years, a large amount of new data has appeared in the literature, so the so-called 'NBS scale' (which will be referred to here as the '1984 scale') is seriously out of date, missing information on about 900 compounds. In addition, since 1991 several important publications (both experimental and theoretical) have presented data indicating that portions of the thermochemical scale, as evaluated in 1984, are in need of re-evaluation. Furthermore, publications from two laboratories (Mautner and Sieck at the National Institute of Standards and Technology, and Szulejko and McMahon at the University of Waterloo) provided extensive data

sets in which equilibrium constants had been determined as a function of temperature, i.e. experimental entropy change determinations had become available.

The results of these experimental proton transfer equilibrium studies indicated that portions of the 1984 gas-phase basicity/proton affinity scale were constricted. For example, in the 1984 scale the difference between the proton affinities of isobutene and ammonia was given as 33.5 kJ mol^{-1} , while according to the newer results, this interval is actually about 50 kJ mol^{-1} . Also, these experimental results indicated that the portion of the 1984 scale representing gas-phase basicities/proton affinities higher than that of ammonia (a portion of the scale that was not 'anchored' by data for a primary standard) was seriously constricted.

Furthermore, according to the 1993 theoretical calculation carried out by Smith and Radom of the proton affinity of isobutene (one of the primary standards for the 1984 scale),

the value for the proton affinity of isobutene used in the 1984 evaluation was too high by about 16 kJ mol^{-1} ; this implied that the previously accepted enthalpy of formation of the $(CH_3)_3C^+$ ion must be in error by this amount. Experimental determinations of that enthalpy of formation carried out by Baer and colleagues and by Traeger soon gave evidence that the theoretical prediction was correct. These experimental and theoretical results corroborated the new equilibrium constant data that indicated that the interval between the proton affinities of isobutene and ammonia was greater by 17 kJ mol^{-1} than previously accepted. All these results had profound implications for the evaluation of the central portion of the thermochemical scales, which had been 'anchored' by taking the proton affinity of isobutene as reference standard.

For these reasons, the present authors undertook a re-evaluation of the entire corpus of data on gas-phase basicities and proton affinities, which now includes data for about 1740 compounds. The database, hosted by NIST can be searched using a variety of parameters (<http://webbook.nist.gov/chemistry>). This effort involved an evaluation of the entire interrelated thermochemical scale. Users of proton affinity data are sometimes confused when a re-evaluation results in a change in the value assigned to a particular molecule, and inquire whether a particular proton affinity value has been re-determined; it is important to understand that, with the exception of the few standards used to 'anchor' the scales, a compound-by-compound evaluation of the scale of gas-phase basicities (or proton affinities) is not possible, and when the entire scale is expanded, contracted or shifted (owing to the appearance of newer, more reliable data),

values assigned to individual compounds will change, even when the original experimental determinations (of relative gas-phase basicities/proton affinities) remain the only source of information about the proton affinity of the compound in question. Although users of the data attach importance to absolute values assigned to particular proton affinity values, it is usually the relative values that are of importance in designing experiments involving proton transfer reactions; it is of primary importance to ascertain that the values being used, be they relative or absolute, are internally consistent.

The evaluation of such a body of interrelated thermodynamic data involves first an evaluation of the thermochemical scales for internal consistency in the three parameters, ΔG^0 (at different temperatures), ΔH^0 and ΔS^0 . Final values assigned for the proton affinities and entropy changes must be consistent with what is known about the thermochemistry of M and MH^+ . The lengths of segments of the scale linking different primary standards (compounds for which eqn [2] can be used to derive an absolute proton affinity value) must of course match the known interval between the 'known' proton affinity values.

The 1998 evaluation of these data took as a starting point an examination of several extensive scales of gas-phase basicities obtained in different laboratories and using different kinds of instrumentation. The existence of such extensive independent data sets, each of which contained numerous checks on internal consistency, was invaluable in establishing confidence in the final evaluated scale. The gas-phase basicity scales were chosen as the starting point for the evaluation, rather than the newly published experimentally determined proton affinity scales (based on van't Hoff plots determined in high-pressure mass spectrometers over the temperature range ~ 450 – 650 K), because there was poor agreement between the relative proton affinity scales determined in the different studies. There are several plausible explanations for the lack of agreement between these data sets determined in different laboratories, including pyrolysis of ions in the high-temperature region (> 600 K), clustering of neutral molecules to the ions in the low-temperature region (< 500 K), or poor characterization of the relative and absolute pressures of the reacting compounds in the high-pressure mass spectrometer ion sources, as demonstrated by Grimsrud and colleagues.

These internally consistent scales of gas-phase basicity data on which the evaluation was primarily based included three data sets obtained at 600 K using high-pressure mass spectrometry, and a very extensive scale determined at 'ambient' temperature using ion cyclotron resonance spectrometry. These independent determinations of the extensive thermochemical ladder were, with a few minor exceptions, in excellent agreement over the central and upper parts of the energy range, except that the older data

yielded scales that appeared to be slightly 'contracted' relative to the recent data, most likely as a result of problems in temperature measurements in the early experiments. A careful evaluation, involving comparisons with analogous experiments where the temperature was carefully measured, permitted a 'standardization' of the various data sets by making appropriate corrections for temperature.

From the evaluated composite gas-phase basicity scale, there was established a 'backbone' scale based on data for some 25 compounds, which included selected primary standards as well as a few other compounds for which entropy changes could be reliably assigned. Primary standards are compounds for which an absolute proton affinity can be established using known enthalpies of formation (eqn [2]). Through the use of this 'backbone' scale, the established scale of relative gas-phase basicities could be tied to absolute proton affinity values. With the 'backbone' scale established, all other published gas basicity data (for some 1700 additional compounds) were related to that scale at appropriate temperatures. Then values for the entropy of protonation (eqn [6]) were assigned, compound-by-compound, to generate the final complete scale of proton affinity values. Finally, the resulting data were examined to verify internal consistency and 'reasonableness' of all the proton affinity and entropy-change values.

In carrying out the evaluation, the scale of proton affinity values produced by Smith and Radom through *ab initio* calculations was an invaluable aid. That scale, of proton affinity values for 31 molecules covering an energy range of about 500 kJ mol^{-1} , effectively spanned most of the experimental scale reported from equilibrium constant determinations, and provided an independent check on the evaluation. Theoretical proton affinity values from this study were available for the 'backbone' scale compounds, and served to verify the evaluations.

Table 1 shows the results of the 1998 evaluation of the gas-phase basicity and proton affinity scales as exemplified by the 'backbone' scale. The results shown include the evaluated proton affinity, gas-phase basicity and entropy of protonation values, the *ab initio* value reported by Smith and Radom and, for comparison, the proton affinity value cited in the 1984 evaluation. Primary standards that anchor the scale are given in *italic* and the footnotes give an indication of the type of experiment that yielded a value for the enthalpy of formation of the protonated molecule, MH^+ (see eqn [2]) used in establishing the absolute proton affinity value. Note that the values adopted for ammonia are essentially the same as those recommended in the 1984 evaluation, and that the portion of the scale above ammonia is expanded by about 8–9% compared to the values assigned in that evaluation. The dramatic change in the proton affinity and gas-phase basicity of isobutene results in a general lowering of values assigned to compounds below isobutene in the

Table 1 'Backbone' scale of proton affinities and gas-phase basicities

scale. Below ethylene in the scale, the changes are less dramatic. It should be mentioned that the scale of gas basicities is not yet well established in the low-basicity region (below the basicities of H₂S and H₂O), where there are major inconsistencies in the data reported from different laboratories.

In Table 1, the standard uncertainties assigned to the primary anchor molecules (italic entries) are the usual root-sum-of-squares combination of individual uncertainties associated with relevant enthalpies of formation and the uncertainty of some key measurement, such as an ionization or an appearance energy. The uncertainties assigned to all the other molecules are based on our best judgment using all the relevant information and a general knowledge of and experience with interlocking thermochemical scales.

Proton Microprobe (Method and Background)

Geoff W Grime, University of Oxford, UK

This article is reproduced from the previous edition, volume 3, pp 1901–1905, © 1999, Elsevier Ltd.

Although the techniques of ion beam analysis (IBA) have been used for many years with broad beams (5–10 mm diameter), it was only in the 1990s that the technology for focusing high-energy ion beams developed to the point where the spatial resolution is comparable to that of other forms of probe beam microanalysis (around 1 μm). The interactions most commonly used require protons with energy of 1–4 MeV for optimum sensitivity, and in this form the instrument is commonly known as the proton or nuclear microprobe.

Using a combination of analytical techniques, the nuclear microprobe can provide simultaneous multi-elemental analysis over the entire periodic table with a spatial resolution of 1 μm , a minimum detection limit of 1–100 ppm depending on the conditions and a quantitative accuracy of 5–20% depending on the type of analysis. Although the penetration depth of MeV protons can be in the region of 100 μm in some materials, the nuclear microprobe is a surface-biased technique since signals are detected preferentially from the near surface region ($\lesssim 10 \mu\text{m}$ depth).

Focusing Systems

The high momentum of MeV ions which gives them their advantage for proton-induced X-ray emission (PIXE) analysis also makes them difficult to focus. In particular, the standard cylindrical magnetic lenses used in electron focusing columns are too weak to be used with MeV ions, and alternative technologies must be sought. Many different arrangements of apertures and electromagnetic fields have been proposed, but the system which has shown consistently the best performance is the magnetic quadrupole multiplet.

Quadrupole lenses have four magnetic poles arranged symmetrically N–S–N–S around the beam axis (Figure 1a). They have a strong focusing action on charged particle beams but, because of the antisymmetry, a single quadrupole lens converges the beam only in one plane and diverges in a plane normal to this. For this reason, two or more quadrupoles of alternating polarity are required to form a point focus. Combinations of two, three and four lenses have been used, as shown in Figure 1b.

Like conventional glass lenses, quadrupole lenses suffer from significant angle-dependent aberrations

which increase the beam diameter and, together with the other parameters of the experiments, these set a limit to the smallest usable beam diameter that can be achieved. This dependence can be loosely expressed as follows:

$$d \propto \sqrt{\frac{\delta R f(C)}{Y B \Omega}} \quad [1]$$

where R is the smallest count rate that is required to perform the experiment with good enough statistics in a reasonable time, δ is the energy spread of the beam, Y is the normalized yield of the analytical reaction being

Figure 1 (a) Cross section of a quadrupole magnet used as a focusing lens for charged particles. Particles travelling in the vertical plane experience a force directed toward the axis; in the horizontal plane the force is directed away from the axis. (b) Combinations of quadrupoles which have been used for micro-beam applications. In the triplet configuration of quadrupole lenses used in the Oxford nuclear microprobe the quadrupoles are excited alternately converging–diverging–converging and the first two magnets have the same excitation (for ease of alignment). Also shown is the object aperture (typically $50 \times 10 \mu\text{m}$) and the collimator aperture used to control the divergence of the beam (and hence the aberrations).

used, B is the brightness of the beam from the accelerator, Ω is the solid angle of the detector and $f(C)$ is some function of the aberration coefficients of the lens system, which in turn depend upon the precise shape and magnitude of the magnetic field in the system; n varies between 2 and 4, depending on the type of the dominant aberration. From this it can be seen that for the best spatial resolution we must accept a low count rate with a high-yield reaction using a beam with small energy spread and high brightness and a detector with a large solid angle. In practice, there is little that can be done to improve these parameters. However, the aberration coefficients of the lens can be minimized to a certain extent by the configuration and precision of construction and alignment of the lens.

Apart from the intrinsic chromatic and spherical aberration present even in a perfect quadrupole field, numerical ray-tracing studies of quadrupole probe-forming systems show that the major contributions to the beam broadening are from small imperfections in the construction and alignment of the lenses, especially departures from exact fourfold symmetry in the poles of the quadrupole magnet and errors in the relative rotational alignment of the lenses. The lenses used in the most successful design are cut from a single piece of high-quality magnet iron to minimize errors due to the assembly of individual components and are mounted on tables permitting precise mechanical alignment to micrometer accuracy (**Figure 2**). Using this system, a spatial resolution of $1\text{ }\mu\text{m}$ can be achieved routinely with a beam current of around 150 pA of 3 MeV protons, sufficient for PIXE analysis. These lenses are available commercially and are now installed in a number of facilities world-

Figure 2 Photograph of the end-stage of a commercially available microbeam focusing system using a triplet of magnetic quadrupoles. wide. Other facilities differ only in scale or details of the layout, and the general principles remain the same.

Analytical Reactions Used in Nuclear Microscopy

Analytical Reactions

Equation [1] indicates that for optimum spatial resolution, high-yield analytical reactions are required. IBA techniques are discussed elsewhere in this volume and here it is shown that the highest cross-section reactions are PIXE and Rutherford backscattering (RBS), which together cover almost the whole of the periodic table. Nuclear reaction analysis has in general a much lower cross section and is not routinely used for high-resolution microbeam applications.

Table 1 presents a comparison of nuclear microbeam analysis using PIXE (microPIXE) with the analogous electron probe microanalysis.

Other Imaging Techniques

Other non-analytical techniques are also available using MeV ions which can be used to give imaging contrast for a sample.

Secondary electron imaging

MeV ions impinging on a surface liberate copious quantities of electrons, and these may be measured using a detector such as a channel electron multiplier to generate images of the sample. The energy of the emitted electrons is relatively low (typically $<1\text{ keV}$) and so they are easily obstructed by surface irregularities. Detecting the electrons at a low (grazing) angle to the surface enhances this effect and allows clear topographic images to be obtained.

Secondary electrons resulting from proton bombardment do not carry any compositional information about the sample, and the spatial resolution is limited by the beam diameter of the ion beam to $1\text{ }\mu\text{m}$ or greater, which is significantly worse than the same technique used in the scanning electron microscope, but the technique can be valuable in helping to relate elemental distributions to the physical structure of the sample.

Scanning transmission ion microscopy (STIM)

MeV ions in matter lose energy gradually by collisions with atomic electrons, so by measuring the energy of particles passing through thin (typically $<30\text{ }\mu\text{m}$) samples, a measure of the electron density along the ion path can be obtained. This can be used as a technique for mapping density fluctuation in samples thin enough to transmit the beam. STIM can be carried out in two modes: with the detector directly in the beam behind the sample (bright-field STIM), the contrast occurs solely

Table 1 Comparison between microPIXE and electron probe microanalysis

	<i>MicroPIXE</i>	<i>Electron probe microanalysis</i>
Primary particle beam	1–3 MeV protons from a nuclear accelerator focused to 1–10 μm with beam current 0.1–10 nA	10–100 keV electrons focused to 10–100 nm with beam current 1 nA–1 μA
Minimum detection limit	1–100 ppm depending on beam energy, sample matrix, elemental overlaps, etc. Limited by count rate	100 ppm–1% depending on beam energy, sample matrix, elemental overlaps, etc. Limited by background
Beam penetration depth	50–100 μm	1–3 μm
Analysis depth	Depends on absorption of emerging X-rays; can be > 50 μm	Similar to penetration depth
Spatial resolution	Equal to beam diameter	Determined by spreading in sample (typically 0.5–2 μm depending on sample thickness)
Quantitative accuracy	Moderate (depends on sample homogeneity). Standardless analysis possible	Good
Other options available	Light elements using RBS and NRA. In-air analysis using external beam facility	High-resolution imaging with Z contrast
Scale of equipment	Medium to large facility (possible shared access to accelerator)	Compact instrument
Availability	< 50 world-wide	Common

RBS = Rutherford backscattering.

NRA = Nuclear reaction analysis.

due to proton energy loss in passing through the sample; with the detector mounted off-axis behind the sample (dark-field STIM), scattered particles are detected and contrast is due to a combination of small-angle scattering and energy loss in the sample. With bright-field STIM, each transmitted proton is a signal (i.e. the yield Y in eqn [1] is 100%) and so the beam current can be reduced to around 1000–2000 particles s^{-1} (~ 0.1 fA) to avoid detector damage and saturation of the acquisition electronics. This is normally carried out by reducing the beam defining apertures in the final lens, and so an added benefit of bright-field STIM is that the beam diameter is reduced and STIM imaging can be carried out at spatial resolutions of the order of 100 nm. For many applications, dark-field STIM is often used to map the sample to locate regions of interest prior to analysis, and this is normally carried out simultaneously with the PIXE and RBS mapping. A STIM image of two mouse red blood cells infected with malaria parasites on a thin plastic film is shown in **Figure 3**.

Ion beam induced charge (IBIC)

Charged particles passing through the junctions of active semiconductor devices create electron–hole pairs which can be detected as charge pulses on the electrodes of the device. Thus scanning a semiconductor device using a microbeam gives the possibility of mapping the active regions of the device either for fault finding or for investigating sensitivity to radiation. This technique is more commonly used with electron beams but the use of MeV ions gives the advantage of the long range, which means that junctions may be studied which are covered by metallization or passivation layers. Like STIM, each particle creates a signal and so it is a high-yield

Figure 3 STIM images of mouse red blood cells (5 μm in diameter), both infected with malaria parasites. The bottom one is well developed and shows the parasite coiled around the inside wall of the cell. Denser or thicker regions of the sample are indicated by lighter colours. Courtesy of Professor F. Watt, National University of Singapore.

technique with the possibility of high-resolution imaging. **Figure 4** shows IBIC images of a gallium arsenide transistor.

External Beam Milliprobe

One consequence of the long range of MeV ions is that they can be brought out of the vacuum system through a

Figure 4 Optical (top left) and IBIC images of a gallium arsenide transistor at three different magnifications (length of side of image area indicated on each area). The IBIC images show the intensity of charge collected between the p-type and n-type contacts, with the highest charge shown as darker. In the highest magnification image, the arrows indicate a $0.8\text{ }\mu\text{m}$ depletion region, showing the resolution that can be achieved using this technique. Reproduced from Breese MBH, Grime GW, Watt F, and Blaikie RJ (1993) *Vacuum* 44: 175, with permission.

suitable exit foil into air, so that large or vacuum-incompatible objects can be analysed. Scattering in the foil and in the air means that the resolution is degraded and, according to the design of the exit aperture, spatial resolutions from $30\text{ }\mu\text{m}$ up to 1 mm can be achieved. The external beam facility used at Oxford University is shown schematically in **Figure 5**. PIXE is the technique most commonly used with external beams, although RBS can be used (with degraded depth resolution because of scattering from air molecules) and nuclear reaction analysis using gamma ray detection can be used to measure light elements because in general the beam currents are higher than in the microbeam. External beam milliprobes are of particular value for analysing archaeological or historical artifacts that it is not possible to sample, or hydrated (or even living) biological samples.

Practical Aspects

Sample preparation

Sample preparation for nuclear microscopy is similar to that required for electron microscopy with the benefit that because of the much longer range of protons in matter (typically $30\text{--}100\text{ }\mu\text{m}$), there is no requirement for ultrathin samples, and in many cases samples can be

Figure 5 Schematic plan view of the external beam analysis facility at Oxford. The beam emerges from the vacuum of the beamline through a $300\text{ }\mu\text{m}$ diameter hole sealed with a thin ($8\text{ }\mu\text{m}$) plastic foil. X-rays emitted from the sample are detected by two detectors mounted at 45° on either side of the beam. One detector is fitted with an X-ray absorber to kill intense low-energy X-ray lines from elements in the sample matrix to ensure good detection limits for the trace elements while the other detector has no absorber and is fitted with a magnetic deflector to ensure that recoiling high-energy protons do not reach the detector. A detector for gamma rays is mounted at 90° to the beam. Below the beamline, a detector for recoiling protons allows the total amount of charge falling on the sample to be monitored. Not shown in this diagram are a video microscope which uses a mirror to view the front surface of the sample during analysis and a low power alignment laser to assist in positioning the sample for analysis.

analysed with little or no sample preparation. **Table 2** summarizes the main types of sample preparation that may be required for nuclear microscopy.

One important consideration for microPIXE analysis is the need to avoid sample treatments which may introduce trace element contamination at the ppm levels detectable using PIXE. This is a particular problem for biological sample preparation, where fixing and staining agents are normally used to preserve the structure of the sample and render visible the regions of interest. For microPIXE analysis of biological samples, the optimum preparation technique is cryo-fixation and sectioning. The structure of the sample must then be determined by a technique such as staining of adjacent sections or STIM imaging of the sample.

Unlike electron microscopy, there is no strong requirement to have a conducting sample, since the high energy of the proton beam will ensure that the beam will not be deflected by the relatively modest potentials

Table 2 Sample preparation techniques for nuclear microbeam analysis^a

Type of sample	Preparation technique
Biological cells	Cryo-fixation on to thin (<1 µm) plastic films
Biological tissue sections	Cryo-fixation followed by cryo-sectioning to a thickness of 5–10 µm and freeze-drying on thin (<1 µm) plastic films
Environmental particles, other particulates and powders	Small particles on filters: analysis <i>in situ</i> on filter membrane. Small particles in bulk: dispersion in dilute resin solution which can be cast into a thin film. Large particles: adhesion to conducting adhesive pad
Mineralogical samples, metals, bone, etc.	Resin embedding and polishing as for electron probe analysis. Insulating samples may need carbon coating

^aBecause IBA is predominantly an inner shell/nuclear technique with most of the signal coming from many atomic layers beneath the surface, there is no strong dependence on surface condition (although ideally the surface to be analysed should be flat). Because of this, many samples can be analysed with no further preparation (especially in the external beam). Other types of sample require some preparation, as summarized in this table.

encountered at the impact point. However, sample charging can be a problem for PIXE analysis, since secondary electrons present in the system can be accelerated to the positively charged impact points and create an enhanced bremsstrahlung background, which degrades the sensitivity. To reduce this effect, insulating samples (e.g. minerals, bone) are usually coated with a thin conducting film, such as carbon.

Pyrolysis Mass Spectrometry, Methods

Jacek P Dworzanski and Henk LC Meuzelaar, University of Utah, Salt Lake City, UT, USA

This article is reproduced from the previous edition, volume 3, pp 1906–1919, © 1999, Elsevier Ltd.

Pyrolysis indicates decomposition caused by thermal energy and, as a process of covalent bond dissociation and rearrangement brought about by heat, represents a form of thermolysis. However, to indicate the relatively high temperature of the process, namely approaching the temperature of a fire, the use of the term 'pyrolysis' – that originates from the Greek: pyr, fire – is commonly used. Primary bond-scission occurring during such processes may generate reactive species which can be involved in further reactions called secondary pyrolysis processes or recombination reactions. The products of pyrolysis are composed of fragment molecules, called pyrolysate, and are generated using a family of devices for performing pyrolysis, namely, pyrolyzers. An analytical technique based on direct coupling of a pyrolyser with a mass spectrometer that allows the detection and analysis on-line of that portion of the pyrolysate which has adequate vapour pressure to reach the detector has been named pyrolysis-mass spectrometry (Py-MS).

It is assumed that, under appropriate conditions, thermal degradation products reflect to a large extent the original structure of the pyrolysed material. Therefore, pyrolysis is utilized as a form of sample pretreatment and is considered as one of the basic approaches during mass spectrometric investigations of complex materials, because both techniques can be fully integrated.

The observation of primary reaction products of high activation energy processes requires both high temperatures and short residence times of the pyrolysate in the hot zone. Flash vacuum pyrolysis performed in proximity to the ion source of a mass spectrometer in many cases satisfies these criteria; however, the design of the pyrolyser plays an important role in the overall performance of the Py-MS system. Reduction of secondary reactions, which tend to decrease both the character and reproducibility of the pyrolytic products, may be achieved by providing short residence times of the pyrolysate in the hot pyrolysis region. The ultimate objective is to obtain

precisely controlled and defined temperature/time profiles of the samples.

The basic steps used to obtain structural information about complex samples by Py-MS are summarized in Figure 1.

Pyrolysis Techniques

Pyrolyzers can be divided into two main categories on the basis of their mode of operation, i.e. the continuous type, where the sample is supplied to a furnace preheated to the final temperature, and pulse mode reactors in which the sample is introduced into a cold furnace which is then heated to the final pyrolysis temperature. In the analytical pyrolysis of solid and some liquid materials mainly pulse mode pyrolyzers are used and the following sections will focus on a few of the most popular pyrolysis techniques utilizing this mode of operation. However, for pyrolytic studies of liquid and gaseous samples continuous pyrolyzers are applied.

Direct Probe Pyrolyzers

Samples to be analysed may be introduced into an MS ion source using heated probe units that allow the material to be deposited directly on straight, folded or coiled filaments or ribbons. Alternatively, a quartz tube or crucible can be placed inside a heater coil and subjected to a selected rate of temperature increase by resistive or inductive heating. The filament or coil is positioned close to the ion source to release pyrolysis products generated under high vacuum conditions.

In principle, any type of magnetic or quadrupole mass spectrometer can be utilized for the analytical pyrolysis of organic materials, if a direct introduction system capable of producing a desired temperature/time profile is available. For example, direct insertion probes (DIPs) and direct exposure probes (DEPs) are widely used for

Figure 1 The various options at each stage of computerized pyrolysis mass spectrometry.

sample introduction and such probes are supplied with control units that allow heating and temperature programming of the sample up to 500–800 °C. Therefore, such modules should be considered as the most readily available probes for Py-MS studies.

The temperature rise time (TRT), i.e. the time required for the pyrolyser temperature to be increased from its initial to the final temperature, can be chosen in the range from several milliseconds to several minutes. Simultaneously, the temperature time profile (TTP), representing temperature as a function of time for a particular pyrolysis experiment, may be easily programmable. Pyrolysis may be carried out at a fast rate of temperature increase, e.g. $10\,000\text{ K s}^{-1}$ in the case of flash pyrolysis, or the sample can be heated at a controlled rate over a temperature range in which pyrolysis occurs using a stepwise, linear or ballistic heating approach characterized by a total heating time (THT) of several minutes or even hours.

To illustrate the relationships among parameters that determine the heating profile for a pyrolytic experiment, a graphical representation of a TTP for an isothermal pyrolysis taking place at the equilibrium temperature is presented in **Figure 2**.

Time-resolved recording of pyrolysate spectra, sometimes referred to as a linear programmed thermal degradation mass spectrometry (LPTDMS), by using a slow heating rate adds additional information (**Figure 3a**) and enables one to perform pyrolysis close to the ion source (**Figure 4** and **Figure 5**). However, considerable contamination of the ion source, together with increased charring and the occurrence of secondary reactions, makes this approach troublesome in many cases.

Curie-Point Pyrolysers

Curie-point pyrolysis takes advantage of fast inductive heating of ferromagnetic materials placed in the high

Figure 2 Schematic representation of the parameters that determine the heating profile in filament pyrolysis, namely temperature rise time (TRT), equilibrium temperature (T_{eq}) and total heating time (THT).

frequency (0.5–1.0 MHz) electromagnetic field generated inside the inductive coil surrounding the pyrolytic reaction tube. This produces fast heating of solid or liquid materials coated on – or gases flowing around – a ferromagnetic sample carrier in the shape of a filament, foil or tube.

Figure 3 Third dimension in pyrolysis mass spectrometry approaches: (a) linear programmed thermal degradation mass spectrometry [LPTDMS – third dimension = temperature]; (b) collisionally activated dissociation of ‘parent’ ions coupled with scanning of product ions using tandem mass spectrometry [MS/MS – third dimension = spectrum of product ions]; (c) laser microprobe mass analyser [LAMMA – third dimension = spatial resolution].

When the high frequency field is switched on, the ferromagnetic carrier inductively heats to its Curie-point temperature (T_c), at which the metal loses its ferromagnetic property, becomes paramagnetic and the heating effect decreases drastically owing to strongly reduced energy absorption from the high frequency field in the coil. This thermostatic effect ensures control of the final pyrolysis temperature (T_{eq}) determined by a sharply defined transition temperature that is specific for the composition of the alloy used, at the point where the

residual energy absorption by eddy currents is balanced by the loss of heat through radiation and conduction.

The TRT for a pyrolyser reactor temperature (Table 1) is determined by the shape and diameter of the carrier, the composition of the alloy, the strength of the high frequency field and its frequency (Figure 6). Since under practical Py-MS conditions pyrolysis may take place before the wire reaches the final temperature, the heating rate is generally thought to have a critical influence on the pyrolysis patterns. However, other factors, such as the choice of the filament cleaning technique and of the solvent, as well as factors that govern either transfer of the pyrolysate to the ion source or that influence ionization conditions, appear to determine the reproducibility of Py-MS more strongly than the temperature/time profile, especially with respect to long-term reproducibility.

Careful attention should be paid to the purity of the surfaces of the pyrolysis filament as well as of the glass reaction tube. Although Curie-point wires are inexpensive and are usually discarded after use, glass or quartz reaction tubes should be carefully cleaned before their next use. The choice of the filament cleaning method may influence the pyrolysis pattern. For example, prolonged heating in water-saturated hydrogen, as a reductive cleaning technique, removes oxide layers on the filament surface which otherwise could have an oxidative or catalytic effect and change the emissivity of the filament surface. However, this cleaning technique can cause severe hydrogen absorption by the metal and this could conceivably influence the pyrolysis process by promoting catalytic hydrogenation reactions. Several other factors, such as substitution of a wire for a ferromagnetic tube, or

wrapping the sample inside a metal foil, produce pronounced changes in the pyrolysis mass spectra of most compounds.

A pyrolysate composed of a multicomponent mixture, under ideal conditions, should allow the pyrolysis products to reach the ionization zone without any loss, degradation or recombination of products during transfer. However, in practice these conditions are never fulfilled owing to the dynamic character of the whole process, which is governed by a complex set of kinetic parameters related to every chemical reaction taking place during the pyrolysis stage as well as to heat and mass transfer conditions, and interactions with walls. In fact, pyrolytic products represent a mixture of compounds characterized by a broad range of relative molecular masses and vapour pressures. As a result, some pyrolysis products tend to remain on the filament in the form of macromolecular,

nonvolatile chars and consequently are inaccessible for further analysis by mass spectrometry. It is well established that the amount of char formed is inversely proportional to the heating rate and can be minimized by avoiding excessively slow heating rates. Another group of compounds is volatile enough to escape from the hot pyrolysis carrier but condenses on the walls of the reaction chamber and transfer lines. Although pyrolysis directly in the ion source is possible, in practice it is difficult to avoid strong contamination of the ion source under these conditions. Therefore, the glass reaction tube surrounding the ferromagnetic carrier serves as a trap for relatively nonvolatile pyrolysis products which otherwise could contaminate the ion source. In addition, these tubes help to obtain maximum signal intensity by producing a forward oriented beam of volatile pyrolysis products which may directly enter the expansion chamber or the ion source, and the ions formed are mass analysed or studied using collisionally induced dissociation (**Figure 3b**).

To broaden the pressure-time profile in the ion source, and thus to enable the recording of a sufficient number of mass spectra to generate a representative averaged mass spectrum of the pyrolysate, an expansion chamber is usually placed between a pyrolytic reactor and the ion source. The expansion chamber should be heated and have chemically inert walls to avoid interaction with pyrolysis products. Quartz or gold-plated expansion chambers, heated to about 150–200 °C are frequently used to provide a buffer volume (**Figure 7**). However, the removal of the expansion chamber and positioning of the reaction tube directly in front of the ion source, together with slowing the heating rate of the wire, allow for sufficient scanning of the pressure-time profile by the quadrupole mass spectrometers (**Figure 5** and **Figure 8**).

In the case of gas-phase pyrolytic reactions the pyrolysis module works as a flow reactor with gaseous molecules passing along the preheated filament into a mass spectrometer. This technique allows quantitative detection of products with half-lives greater than 1 ms.

Figure 7 Scheme of an automated Curie-point Py-MS system with a dedicated minicomputer. Samples are selected by a pickup arm from the turntable and positioned inside the high frequency coil. The pyrolysate diffuses via a buffer volume into the mass spectrometer where the molecules are ionized and mass-analysed. Laser Pyrolysers

Laser pyrolysers achieve very high TRTs together with the possibility of characterizing very small surfaces. With a spatial resolution as high as $0.5\ \mu\text{m}$ (Figure 3c) and sample quantities in the range of picograms such instruments permit analysis of very small objects, for example a single bacterial cell. A high power ($\sim 10^9\ \text{W cm}^{-2}$) beam pulse from a commercially available laser microprobe mass analyser (LAMMA) is provided by a Nd:YAG laser and focused on the sample by a microscope objective.

Short pulses ($\sim 15\ \text{ns}$) create a plasma of positive and negative ions which are mass analysed by a time-of-flight (TOF) mass spectrometer. Although the mechanism of laser-induced ionization and volatilization of solids is not well known, it is established that the duration and shape of the laser pulse affect the nature of the volatilization process. The region of direct impact of the laser on a sample is associated with high temperatures and consequently only small atomic and molecular fragments are emitted from this region. In the region immediately adjacent to the area of direct laser beam impact, a temperature gradient governed by a complex set of pyrolysis reactions will occur, resulting in emission of higher relative molecular mass products.

Analytical Systems Based on Pyrolysis-Mass Spectrometry

Analytical systems based on Py-MS are intended to perform pyrolytic reactions and to analyse the composition of the resultant pyrolysate by mass analysis of ions formed through the ionization of its components molecules. The structural complexity of the spectra recorded is usually considerable, owing to the formation of fragments with the same nominal mass from originally different components and the absence of reliable separation procedures. In addition, the observed complexity originates from secondary fragmentation processes; hence various techniques have been used that minimize these effects. These include low-voltage electron ionization (LVEI) with 10–15 eV electrons instead of the standard 70 eV; chemical ionization (CI) with different reagent ions under vacuum or at atmospheric pressure and field ionization (FI). Despite the complexity of the mass spectra recorded, here referred to as mass pyrograms, even low-resolution spectra frequently provide structural information through the presence of characteristic ions or ion series. However, to provide clarity, many other techniques can be used, e.g. time/temperature resolved thermal degradation/pyrolysis MS, high-resolution mass spectrometry (HRMS) and tandem in space or

Figure 8 Curie-point pyrolysis MS-MS system: pyrolysis products diffuse into the ion source where the ions are formed by electron-impact (EI) ionization and analysed by a triple quadrupole mass analyser (Q1–Q3). Different modes of ion analysis: (a) EI spectrum of a pyrolysate; (b) neutral loss spectrum; (c) single ion spectrum; and (d) collisionally induced dissociation spectrum of a 'parent' ion.

Figure 9 Schematic representation of six on-line pyrolysis-mass spectrometry configurations. (*) Ionization zone; (●) pyrolysis zone.

tandem in time mass spectrometry (MS^n , $n \geq 2$) following collisionally activated dissociation of selected ions.

A schematic overview of some of the most frequently reported experimental arrangements of pyrolysis zones with respect to ionization regions is given in **Figure 9**. In configurations A–C the reaction zones are under vacuum, whereas in D and E pyrolytic regions are kept at near-ambient pressures and for F at high pressure. Examples of integral zones include pyrolysis-field desorption in the ion source of a mass spectrometer (**Figure 10**), laser

pyrolysis/photolysis/desorption/ionization mass analyser (LAMMA) and, to some extent, in-source pyrolysis chemical ionization MS. This type of configuration allows the detection of large, and frequently highly informative, molecular or fragment ions from nanogram quantities of a sample. The use of field-desorption ionization coupled with HRMS, as well as field ionization techniques which have been developed to produce a high intensity of molecular ions and to reduce fragmentation of polar compounds, are well suited for the molecular characterization of polymeric building blocks. This approach is characterized by a very short residence time of the pyrolytic sample in the reaction zone (10^{-11} s), thus allowing for detection of short-lived primary products.

The other way to avoid losses of higher relative molecular mass components and less volatile thermal fragments, which are unable to enter the ion source owing to the condensation, is to place a pyrolysis probe very close to the ionization source, thus providing minimal separation between reaction and ionization zones. Typical examples of this type of configuration are shown in **Figures 4, 5, 8 and 11**; however, vacuum TG-MS systems also fulfil the criteria of the configuration in **Figure 9b**. The so-called in-source pyrolysis produces compounds that can be ionized either under EI, CI or FI

Figure 10 Field desorption (FD) pyrolysis in the ion source of a mass spectrometer. The place of pyrolysis and ionization is identical. Reproduced by permission of Elsevier Science from Schulten H-R (1977) Pyrolysis field ionization and field desorption mass spectrometry of biomacromolecules, microorganisms, and tissue material. In: Jones CER and Cramers CA (eds.) *Analytical Pyrolysis*. Amsterdam: Elsevier Science.

conditions. The application of such techniques for analysis of bacteria, lignocellulosic materials and polysaccharides has been documented, indicating additional advantages of this technique derived from the slower heating rate and the absence of mixing in an expansion chamber that represents the type of configuration shown in **Figure 9c** and includes a specially designed, fully automated Curie-point Py-MS system with an expansion chamber (**Figure 7**) but frequently represents the result of adapting an existing gas inlet manifold for on-line reaction studies.

The temperature-resolved data acquisition mode of operation provides additional layers of information. The evaluation of time-resolved mass spectral data of temperature-programmed pyrolyses include the shape of the total ion current profile, variations of the average relative molecular mass of volatilized pyrolysis products as well as the selection of characteristic mass signals, typical for distinct pyrolysis intervals. In addition, the differentiating key signals can be easily found and used for further investigation, e.g. temperature-resolved profiles of single ion intensities or specific sets of ion profiles can be selected to study pyrolysis processes of distinct sample components. Such components can be selected using chemometric techniques, e.g. factor or principal component analysis of time-resolved series of spectra combined with the 'numerical extraction' of chemical components, as revealed by the calculated mass spectra.

The identity of mass peaks or assignment of chemical structures to mass signals is complicated by the presence of isobaric fragment ions and isomeric structures of molecular ions. However, the presence of isobaric ions with a different composition can be investigated by HRMS, and pyrolysis product identification may further

Figure 11 Instrumental configuration for laser pyrolysis EI ionization mass spectrometry. Reproduced by permission of Elsevier Science from Meuzelaar HLC, Windig W, Huff SM, and Richards JM (1986) *Analytica Chimica Acta* 190: 119–132.

be supported by using MS-MS and/or GC-MS methods. Nevertheless, the combination of various ionization techniques, HRMS and, especially, MS-MS (**Figure 8**) can provide the extra specificity required for the analysis of complex materials.

If the pressure drop across the orifice or short capillary tube in a mass spectrometer sampling system exceeds a critical value of about 2.5, the flow velocity will reach the speed of sound and the flow beyond the exit expands into a

Figure 12 Schematic of a pyrolysis vapour generator coupled to a molecular-beam mass spectrometer sampling system. Reproduced by permission of the American Chemical Society from Evans RJ and Milne TA (1987) *Energy and Fuels* 1: 123–137.

supersonic ‘free’ jet, thereby producing a molecular beam (MB). This process is characterized by extreme collisional as well as internal energy (rotational and vibrational) cooling caused by isentropic and adiabatic expansion of a gas after crossing the sampling orifice (Figure 9d). A typical molecular-beam mass spectrometer (MBMS) sampling system coupled to a pyrolysis vapour generator is shown in Figure 12. It consists of a conical, extractive sampling probe, a skimmer to collimate the molecular beam and a line-of-sight MB inlet into the ion source of the mass spectrometer. Ions formed by EI ionization are directly mass analysed – or additionally studied using collisionally induced dissociation – with quadrupole mass filters or other mass spectrometric analysers.

The remaining two configurations (Figure 9e and Figure 9f) are characterized by inherently lower molecular conductances and are usually referred to as pyrolysis GC-MS or represent a form of mass spectrometric monitoring of high pressure reactors, including industrial-scale units.

Reproducibility and Data Analysis Procedures

Short-term reproducibility of pyrolysis-mass spectra recorded during Py-MS studies is usually good and

Table 2 Factors that possibly influence long-term reproducibility

Sample preparation	Filament heating	Product transfer	Mass analysis
Cleaning of sample carrier	Temperature rise time	Inlet temperature	Ionization
Solvent/suspending liquid	Equilibrium temperature	Residence time	Extraction
Sample size	Total heating time	Surface activity	Transmission

variations of peak intensities to within 5% are readily achieved. However, interlaboratory and long-term reproducibilities are not well evaluated. Some of the factors that influence long-term reproducibility and which should be carefully evaluated in interlaboratory comparisons are presented in Table 2.

Progress in the design of mass spectrometers and the availability of on-line computer systems has allowed the integration of Py-MS data acquisition with multivariate mathematical data reduction methods into a single analysis technique. Such an approach combines rapid analysis capability with expert system or pattern recognition-based data evaluation (Figure 13).

Applications of Py-MS Methods

Natural Products

Natural products in general, and organic natural products in particular, are characterized by a high degree of complexity, thus requiring highly specialized analytical methods which tend to be labour intensive, lengthy and expensive. However, in the early 1960s the search for extraterrestrial life, as part of the new space probe programmes, prompted the development and application of pyrolytic methods to complex biomaterials and micro-organisms. The combination of pyrolysis and mass spectrometry was found to be an especially powerful tool to produce structural information about the molecular building blocks of many natural products that are solid, high relative molecular mass, insoluble, homo- or heteropolymeric materials. Moreover, advantages of Py-MS methods include sensitivity, specificity and speed. However, it should be noted that inorganic substances, such as salts and metal cations, may have a catalytic influence on the formation of organic pyrolysis products and that highly heterogeneous, cross-linked materials will not yield 100% pyrolysate but will ‘disproportionate’ into volatile matter and char. For example, it was shown that

Figure 13 Time-resolved Curie-point pyrolysis MS total ion signal profile of a coal sample obtained at a heating rate of 100 K s^{-1} (a) and the 'deconvolution' of the second maximum (at 510°C) into at least three components (b–d) by means of factor analysis (b). Tentative interpretation of components a–d was based on comparison of numerically extracted spectra with the actual spectra of maceral concentrates. Numbers in parentheses show the percent of the total variance for each component. alkali metals affect the thermal activation of polysaccharides, which can result in a total loss of oligomer information.

To make quantitative estimates of the portion of sample analysed, it is advisable to determine the amount and approximate composition of the pyrolysis residue. Generally, volatilization tends to decrease with the increasing polarity of a material – owing to the presence of additional intermolecular forces. As a consequence, pyrolysates of complex natural materials, e.g. soil particles, will under-represent functional groups containing polarized bonds. To overcome these problems, various on-line and off-line derivatization techniques have been developed. For example, addition of a tetramethylammonium hydroxide (TMAH) solution to a sample deposited on a pyrolytic wire allows a wide range

of O-, N-, S- and P-containing polar compounds to be analysed owing to the largely increased volatility of methylated products formed during the pyrolytic methylation step. However, in some cases, by using Py-MS systems with integrated reaction and ionization zones, high molecular mass oligomers can be recorded, as illustrated in **Figure 14**. In this case a series of ions representing 1,6-anhydro-oligosaccharides, ranging from monomer to dodecamer, obtained by in-source pyrolysis chemical ionization of cellulose can be observed.

In other cases, highly specific derivatives may be produced under pyrolytic conditions. For example, diketopiperazines (DKPs) are formed during the thermal decomposition of oligopeptides that range from two to six amino acids. In **Figure 15a** a pyrolysis mass spectrum of

Figure 16 Curie-point pyrolysis EI mass spectrum of *B. anthracis* showing (a) fragment ions of a series $[R-C=O + 74]^+$, representing the contribution of particular types of fatty acid residues to the overall profile of bacterial fatty acids, and (b) molecular ions of dehydrated diacylglycerols (diacylpropenodiols) originating from cellular phospholipids.

product ions derived from the parent ion at m/z 260, obtained during Py-MS of phenylalanyl-leucine is presented, whereas **Figure 15b** shows general fragmentation pathway of these dipeptide-derived ions. The results showed a variability in the relative intensities of the various DKPs which depends on the amino acids involved in the cyclization process and their position in the peptide. Identification of pure dipeptides from DKP formation observed in Py-MS is rapid and involves no derivatization or complicated sample preparation procedures.

Bacteria

Classification and identification of microorganisms based on rapid and specific methods for determining the chemical composition have proved to be a valuable approach in microbiology. The identification of many chemical constituents that show a degree of specificity suitable for chemotaxonomic and/or diagnostic purposes made it clear that improvements in methods of sample preparation play an important role in fully utilizing the high speed and specificity offered by MS.

Py-MS is commonly applied for bacterial fingerprinting, i.e. classification of characteristic signal patterns followed the first reports published in the 1960s on the applicability of analytical pyrolysis techniques to clinical and pharmaceutical microbiology. Application of Py-MS as an independent tool for the characterization and identification of bacteria represents an alternative

approach that may provide important information for the discrimination of closely related microbial strains that is difficult to obtain by other techniques. Hence, the objectives of most projects were focused on the differentiation and classification of bacterial strains at either the genus, species or subspecies level and subsequent identification of unknown strains. The structural information which can be obtained from the pyrograms and the quantitative nature of the data allow them to be successfully used not only for both the chemical characterization of whole cells and cellular components but also in quality control and screening.

Important advantages of Py-MS techniques are the small sample size required, the high sample throughput, and the ready compatibility of the data with computerized evaluation. To classify the Py-MS profiles of various bacteria an expert system was constructed using multivariate statistical analysis. However, various aspects should be taken into consideration during application of this technique in microbiology, i.e. instrumental and biological. Standardization of instrumental conditions is essential to achieve an acceptable level of long-term and interlaboratory reproducibility while standardized culturing and sampling are required to minimize biological heterogeneity among the samples. Sampling directly from the solid medium, and thus avoiding further manipulations, proved to be superior to methods involving the washing of harvested bacteria to remove culturing media, often followed by lyophilization and resuspension of cells in sterile water. In addition, the pyrolytic derivatization approach allows one to utilize chemical derivatization for some groups of less volatile compounds to convert them into a suitable form for MS analysis.

By the 1990s the search for characteristic pyrolysis products of complex biomolecules with the use of GC-MS and MS-MS instruments had firmly established the usefulness of analytical pyrolysis techniques when used in a biochemical marker detection, rather than in a 'fingerprinting' mode. Either direct pyrolysis followed by analysis of thermal fragmentation products or, alternatively, chemical derivatization followed by analysis of the derivatized products can be used to transform non-volatile polar and macromolecular components into characteristic chemical markers with sufficient volatility for MS analysis. The success of analytical pyrolysis was based on its abilities to detect compounds that are unique for particular groups of microorganisms.

For example, diacylpropenodiols, originating as pyrolytic products of bacterial phospholipids (PLs), under the standard conditions of EI ionization form molecular ions suitable for the evaluation of the acyl residue composition of PLs (number of carbon atoms and double bonds). In addition, the types of fatty acids involved in the composition of PLs may be determined using fragment ions of the general formula $[R-C=O + 74]^+$ (**Figure 16**). To

Figure 17 Temperature-programmed pyrolysis-mass spectrometry analysis of the sheen on anti-static matting: (a) temperature-resolved total ion current signal profile of pyrolysis products obtained; (b) mass spectrum of component a; (c) component b; (d) component c. perform detailed structural determinations of individual fatty acids, pyrolytic *in situ* hydrolysis-methylation of whole cells with tetramethylammonium hydroxide (TMAH) was applied. This procedure, performed on a micro-scale on the surface of a pyrolytic wire, was shown to produce results which were qualitatively and quantitatively identical, or near-identical, to those from conventional methods. However, the Py-MS approach allows one to shorten the time needed to obtain this type of chemotaxonomic information by a few orders of magnitude. In addition, this method provides additional information, owing to the possibility for simultaneous analysis of other cell components, e.g. mycolic and mycosteric acids from mycobacteria or of dipicolinic acid methyl

ester from bacterial spores in addition to a plethora of pyrolytic products of proteins, sugars and nucleic acids.

Synthetic Polymers

Bond cleavages that occur as a result of thermal excitation of all vibrational modes of the polymer lead to the formation of macroradicals that undergo secondary reactions via intra- or intermolecular mechanisms. Investigations of polymer decomposition mechanisms using Py-MS have been widely used to characterize the polymer microstructure and the accumulated knowledge applied to unknown polymers and to investigations of polymer decomposition products.

Plastics and rubbers are mainly copolymers or blends of different polymers, and commercial products contain other additives, namely, plasticizers, antioxidants, pigments, cross-linking agents, flame retardants and many other components that are used to obtain desired physical properties of polymeric products. Hence, the Py-MS technique can be used as a method to quickly examine an unknown polymer sample to determine its composition, thus providing a rapid means of identifying copolymers, blends and additives in industrial rubbers and plastics. The investigation of polymer decomposition mechanisms allows for the qualitative and quantitative characterization of unknown polymers and Py-MS should be considered as a useful tool for studies of polymer microstructure. In **Figure 17** the results of temperature-programmed pyrolysis-MS analysis of the 'sheen' on anti-static matting are presented – showing the capabilities of a Py-MS system to perform rapid structural investigations of polymers.

In spite of the complexity of the starting material, Py-MS allows one to analyse even microgram quantities of analytes, thus providing the means for the investigation of heterogeneous products and for direct analysis, circumventing the need for dissolving or pre-separation of components. In addition, different parts of heterogeneous materials may be studied separately and pyrogram patterns may be used to compare related materials. Thus, the Py-MS technique can also be used for rapid investigation of polymer samples to identify copolymers, blends and selected additives for forensic applications.

Flash desorption of oligomers relies on kinetic competition between evaporation and thermal decomposition. Molecular ion signals from the MS have been used to determine the average molecular masses and distribution of oligomers, whereas expert systems can be used to establish mechanisms for the thermal degradation of polymers, e.g. to determine the relationships between polymer structure and the corresponding Py-MS spectra.

Quadrupole mass spectrometers (often referred to as quadrupole mass filters because of the way they operate) are the most successful example of the class of mass spectrometers called 'dynamic'. Their performance depends upon a dynamic interaction of ions with time-varying electric fields. Most classes of spectrometers are 'static' and use either the interaction of fixed magnetic and electric fields or 'time-of-flight'.

The quadrupole mass spectrometer derives its name from the nature of the electric potential which is quadrupolar in the direction transverse to ion injection, i.e. dependent on the square of the distance from the centre of the field. The field is achieved by using four parallel rods as schematically illustrated in **Figure 1**.

This article begins with a brief history. It then explains the principles of operation of this mass spectrometer. The idealized view of its operation has to be tempered by consideration of some real-world situations that influence

performance, such as the finite length of the field, the inevitability of fringing fields and field imperfections. Observations of performance and its limitations are illustrated. The applications section deals with residual gas analysis, gas chromatography and liquid chromatography mass spectrometry (GC-MS and LC-MS), collision induced dissociation using triple quadrupoles (MS/MS) and inductively coupled plasma mass spectrometry (ICP-MS) used for elemental analysis.

A History of Development

The possibility of using quadrupole radiofrequency fields for mass analysis was first suggested in 1953 by Paul and Steinwedel and in a US government report by Post. The first practical implementation was by Paul and

Figure 1 A schematic illustration of a quadrupole mass spectrometer. Ions that are to be filtered to identify the presence of a particular mass are injected in the direction of the axis of the instrument. If the combination of radiofrequency and direct voltages applied to the rods is correctly chosen, only ions of one particular mass to charge ratio (m/z) will be successfully transmitted to the detector. Φ_0 defines an electric potential.

co-workers in 1958. This work became the foundation for the field. Wolfgang Paul was awarded a share of the Nobel Prize for physics in 1989 for the development of the ion trap technique that also used quadrupole fields.

Early quadrupole mass filters were very limited in mass range and resolution but their physical simplicity and the absence of a magnet made them attractive for upper atmosphere and space applications. Major development occurred in the 1960s inspired by this application. This same period also coincided with a rising demand for residual gas analysers because ultrahigh vacuum technology began to have routine application, first in research laboratories and later in production equipment, especially in semiconductor processing. Gradually the quadrupole mass filter became the dominant instrument for this application and remains so today.

Quadrupole performance slowly improved but in the 1970s new applications to organic analysis and particularly the implementation of the combination of GC and MS placed increasing emphasis on better understanding of how the instruments worked in order to overcome their limitations. Computer simulations of performance became important. Combined with detailed experimental analysis, these led to a much improved knowledge of real-world quadrupoles with fringing fields and field imperfections. An important advance came with the application of phase space dynamics for calculating quadrupole performance. The new advances were incorporated in the classic textbook of the field written by Dawson and various collaborators and published in 1976. This book was re-issued by the American Institute of Physics in 1995 as a 'paper-back classic'.

In the 1980s and 1990s, the limits to quadrupole performance have been pushed back by precision manufacture and careful source design. A mass range of up to 2000 or more is commonly achieved with unit mass resolution. For LC-MS applications the mass range may reach 4000. There have been equally significant improvements in trace analysis capability based on a combination of sensitivity and more perfect peak shapes. High-performance quadrupole mass spectrometer manufacture has come to demand very high precision.

Principles of Operation

The Perfect Field

In a perfect quadrupole mass filter field, motion in the x and y (transverse) directions is independent. There is no field in the axial direction and motion is unchanged along the axis. Both x and y motion are governed by the Mathieu equation (see the Further Reading section for the derivation of these equations);

$$d^2u/d\xi^2 + (a_u - 2q_u \cos 2\xi)u = 0$$

i.e. where u represents x or y and where

$$a_x = -a_y = 8zU/mr_0^2\omega^2, \quad q_x = -q_y = \frac{4zV}{mr_0^2\omega^2}$$

the applied voltages across the quadrupole are a direct voltage U and an alternating radiofrequency voltage of $V \cos \omega t$ and the minimum separation between opposite pairs of electrodes is $2r_0$. The mass to charge ratio of the ion is m/z . Time is expressed by $\xi = \omega t/2$, where t is in seconds. For ion transmission the ions must have finite amplitude of oscillation in both x and y directions so that they do not strike the rods, i.e. the trajectories are both 'stable'.

Combinations of a and q values that give stable motion are shown in **Figure 2**. There are several areas of simultaneous stability. The one near the origin is commonly used but the higher zones have been examined both theoretically and experimentally, especially in the search for peak shapes with more abrupt fall-off at the edges for applications in trace analysis. The quadrupole uses a sinusoidal alternating field. In principle any alternating field is possible but the higher harmonics may lead to complexity in the behaviour of the ions. The RF frequency is generally in the range of 1–2 MHz.

Mass selection is obtained by choosing a ratio of q/a so that only a narrow region of the stability zone near the apex ($a = 0.23699$ and $q = 0.706$) is intersected by the operating line using $q/a = \text{constant}$. For a given RF and DC voltage, ions of different mass to charge ratio (m/z) appear at different points along the line. Mass scanning is carried out by altering the values of U and V while maintaining their ratio constant to bring ions of different m/z into the tip of the stability region. This would give a spectrum of constant resolution ($M/\Delta M$). In practice a resolution that increases with mass is preferred and the ratio q/a is adjusted electronically throughout the mass scan in order to achieve more or less constant peak width. An alternative to voltage scanning would be to scan the frequency but this is rarely done because of technical difficulties in covering a large mass range.

This simple description implicitly assumes that the length of the quadrupole is infinite so that all ions with stable trajectories are differentiated from those with unstable trajectories. In practice, resolution may be limited by the length of the field. It is found that $R_{\text{max}} = n^2/b$, where R_{max} is the maximum attainable resolution and n is the number of RF cycles the ions spend in the field. The parameter b depends upon the source and on the fringing fields. A value of 25 is not unusual; a value of 10 would be an excellent performance. High resolution is favoured for ions of low axial velocity (lower energy ions but, fortunately, also higher mass ions). One is limited, however, in reducing axial ion energies by the detrimental influence of fringing fields.

Figure 2 Zones for stable trajectories in both x and y transverse directions expressed in terms of the parameters a and q which are related to the m/z ratios of the ions. (a) General zones of stability, (b) a detail of the zone commonly used. The iso-beta lines are related to frequencies of ion oscillation.

The Real World: Transmission and Fringing Fields

In the real world, there are inevitably fringing fields at the entrance to and the exit from the mass filter. Ion motion in these fields can be very complex and the motion in each of the three coordinate directions becomes coupled. Very low energy ions may be reflected or even trapped in the fringing fields. However, a good theoretical approximation in most cases is to assume a linear increase of the x and y direction fields as the

Figure 3 Phase space acceptance diagrams showing the initial conditions of transverse displacement and velocities that lead to ion transmission at 100% and 50% of the initial phases of the RF field. (a) x-direction, (b) y-direction. This is for the centre of a peak and for ions spending two RF cycles passing through the fringing fields. The displacement from the axis is measured in units of r_0 and the velocity in terms of r_0/ξ .

entrance is approached. The fringing fields extend over a distance comparable to the filter radius. The y -direction (a, q) values in the fringing field correspond to intrinsically unstable ion trajectories. If too much time is spent in the fringing fields, ion amplitudes will increase and the effective aperture of the spectrometer will be reduced.

The finite diameter of the field (r_0) means that ions are only 'accepted' for transmission when they enter the field with a small initial transverse displacement from the axis and small transverse velocities. The combination of displacement and transverse velocities that are possible defines the 'acceptance' of the instrument. The acceptance and so the overall sensitivity becomes smaller as the resolution is increased. The acceptance is calculated using phase space dynamics.

The sensitivity of the mass spectrometer is best expressed in terms of a phase space diagram as shown in **Figure 3**. This shows the initial combinations of transverse position and transverse velocity that will result in ion transmission. In practice, this depends upon the initial phase of the field when the ion first experiences

the field. The figure shows the x and y 'acceptances' for transmission in 100% of the initial phases, 50%, and so on. At higher resolutions the acceptance area decreases.

At a given resolution, combining the x and y acceptances together gives an indication of sensitivity for different numbers of RF cycles spent in the fringing fields giving a diagram such as that in **Figure 4**. This shows that fringing fields can be advantageous if properly chosen. There have been many attempts to tailor fringing fields for optimum performance, such as using retardation of ions after they enter the field or by adding RF only sections at the ion entry (the 'delayed DC ramp'), or by using specially shaped electrodes.

If the relative ion transmission is measured versus resolution for a particular mass number, there will be a curve such as that in **Figure 5**. If the source is evenly illuminated, at low resolution the source emittance will be less than the quadrupole acceptance and the transmission will vary little with resolution. Also the peaks will tend to be flat topped. At some point the acceptance

Figure 4 Combined phase space acceptance areas for x and y directions as function of the length of the fringing field (expressed as the number of RF cycles that the ions spend within the fringing field). This illustrates how sensitivity may vary depending on ion velocity.

will become limiting and transmission will tend to fall with the square of the resolution (taking fringing fields into account). Finally, at the length limitation of the quadrupole the transmission drops abruptly with resolution. Curves (a) and (b) illustrate different ion energies. In some cases, the source emittance may be rather diffuse or may not be evenly illuminated, then quite different transmission versus resolution behaviour will be observed.

The Real World: Field Imperfections

There are inevitably other departures from the perfect fields and these become more and more important at high resolution. Displacement of one or more rods from the ideal position is the simplest case. This leads to higher order terms in the expression for the electrical potential. One rod displaced would give predominantly third-order or hexapole correction terms. Opposite rods displaced give fourth-order or octopole terms. These imperfections limit the resolution that is attainable, i.e. even if n is increased, the resolution will not increase further. There have been various theoretical and more limited experimental studies of these effects. The field faults may also cause badly shaped or even split peaks because of non-linear resonances in the ion oscillations at certain critical (a , q) values.

Other field faults may arise from nonparallel rods (bending or bowing) or from errors in the electrical waveform. It is common to substitute round rods in the quadrupole for the ideal hyperbolic ones. Round rods are easier to precision-manufacture. If the diameter and positioning of the rods is correctly matched, field faults

Figure 5 A typical example of transmission efficiency versus resolution for an instrument with a well-defined source emittance. There are three regions of transmittance as resolution is increased. (I) Sensitivity is source limited, (II) sensitivity is filter acceptance limited, (III) resolution is length limited (number of cycles in the field) and (IV) resolution is limited by field imperfection.

are minimized and only sixth-order distortions are produced. These are not expected to significantly influence performance. However, there is controversy over this choice of round and hyperbolic rods with many assertions being made but little solid experimental evidence. One confusing factor is that other field faults (e.g. from rod positioning) may be more serious when using round rods.

Observations of Limits to Performance

Figure 6 illustrates some of the data from an extensive examination of performance of a particular quadrupole. These data demonstrate most of the features discussed

Figure 6 Some examples of performance measurement for a particular quadrupole mass filter showing how the limiting resolution varied with the number of RF cycles in the field. The ultimate resolution reached was dependent on frequency and mass number.

above. In addition, there is an ultimate limit to achievable resolution set by the perfection of the quadrupole field.

Similar performance data have been generated for operation using other regions of the stability diagram such as near $a = 0$, $q = 7.5$ or $a = 3$, $q = 3$. These regions may have interest for specialized applications.

Applications

Residual Gas Analysis

One of the first uses of quadrupole mass filters was for residual gas analysis in high-vacuum chambers. An electron beam ionizes the background gas and a mass spectrum is recorded with the quadrupole. This allows determination of the composition of the background gas and, after calibration, the partial pressures of each of the components, such as N_2 , O_2 , H_2O , etc. Because only light gases are generally involved, the mass range of the quadrupole need only be 100–200 m/z . The compact and rugged construction of a quadrupole with purely electronic scanning makes quadrupoles particularly attractive for this application. Often the quadrupole is mounted on a flange which is simply bolted onto the vacuum chamber. Sometimes a pressure reduction stage is used. Modern systems have computer-controlled scanning and allow the possibility of searching libraries to match an unknown spectrum.

GC-MS

A considerable fraction of quadrupole mass spectrometers sold today are used as detectors for GC to identify and quantify trace levels of organic compounds. Environmental analysis and drug testing of athletes, for example, rely extensively on GC-MS. Organic compounds separated by a gas chromatograph elute into the ion source of a quadrupole mass filter. Ions are formed either by electron impact (EI) or by chemical ionization (CI). In EI, positive molecular and fragment ions are usually formed. The resulting mass spectrum gives a fingerprint of the compound. Unknown compounds can be identified by searching a library of spectra. In CI, analytes react with a reagent ion present in excess to produce either positive or negative molecular adduct ions, usually with minimal fragmentation. The combination of the retention time on the chromatograph and the appropriate molecular mass is often sufficient to identify trace analytes.

Quadrupole mass filters have become the standard for GC-MS because they are easily interfaced to computers, scan rapidly on a time scale compatible with peaks eluting from a GC, require only medium vacuum (10^{-5} mbar), are compact, and are of comparatively low cost. Gas chromatography is restricted to relatively volatile compounds with moderate molecular masses and so the

m/z range of a quadrupole used as a detector for GC is usually ~ 500 – 1000 . A complete EI spectrum can be obtained on ~ 10 pg of an analyte. If only ions of one m/z are monitored ('single ion monitoring'), with CI, the detection limits can be lowered to low femtogram levels. Alternatively a few selected m/z values (say four) corresponding to the major peaks in the spectrum of a targeted compound can be monitored by switching the quadrupole between these m/z values without scanning intervening regions ('multiple ion monitoring'). The ability to switch a quadrupole from full scans to single ion monitoring to improve detection limits is an advantage over other methods where a complete spectrum must be acquired (TOF, ion trap ICR). A quadrupole system dedicated to GC/MS can be quite compact, often smaller than the GC itself.

LC-MS

To separate and detect less volatile, more polar, more labile or higher molecular mass compounds, the GC is replaced by an LC. A number of ion sources have been used for LC-MS but two dominate: atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI). In APCI, solvent and analytes eluting from the LC are sprayed into a heated tube at atmospheric pressure where they rapidly vaporize. Ions of the solvent are formed in a corona discharge. Typically in positive-ion mode these are protonated. These ions then transfer charge to analytes to produce molecular ions. In ESI the solution eluting from the LC is passed through a metal capillary that has a high voltage applied to it (3000–5000 V). Charged droplets emerge from the capillary tip at atmospheric pressure and lose solvent through evaporation, leading to the formation of gas phase ions characteristic of the ions in solution. Compounds that are present as simple ions in solution (M^+ , M^- or MH^+ , MH^-) give the same ion in the gas phase. Protein ions with molecular masses 5000–100 000 acquire multiple charges to produce ions with m/z ratios of <4000 (Figure 7) that can still be analysed by a quadrupole. Molecules with intermediate molecular masses produce ions with a few charges, depending on the number of basic residues and their pK_a values. Conventional ESI operates best at flow rates of 1 – $10 \mu\text{L min}^{-1}$. LC flow rates are usually considerably higher ($\sim 1 \text{ mL min}^{-1}$) so the output of the LC is often split, with a fraction of the flow going to the ESI source.

APCI and ESI produce ions at atmospheric pressure. These are transferred into the vacuum system of a quadrupole mass filter with two or more stages of differential pumping. The ability to operate a quadrupole at moderate pressures of $\sim 10^{-5}$ torr means only modest, lower cost vacuum pumps are required. ESI and APCI generally produce protonated molecular ions. As in GC-

Figure 7 The mass spectrum of the protein cytochrome c (M_r 12 200) obtained with an ESI ion source and quadrupole mass filter. The isotopic structure of the peaks is not resolved. Each peak is identified by the number of protons attached to the protein.

MS, for targeted compound analysis the quadrupole is operated in 'single ion' mode to monitor the m/z of interest. Fragment ions can be formed by applying high electric fields to the ions in the ion sampling region. These fields accelerate the ions through the locally formed high density of gas causing collision-induced dissociation. If the system is operated in this mode, a full scan over the spectrum of an analyte can be obtained. Alternatively multiple ion monitoring can be used for a few m/z values of interest and detection limits of a few picograms of organic compounds are possible.

One application of LC-MS is to identify proteins. The molecular mass of the protein is determined by ESI-MS. A proteolytic enzyme such as trypsin is then used to cleave the protein into peptides. These are separated by LC and their molecular masses determined. These molecular masses, the molecular mass of the protein and specifying the residues cleaved by the enzyme can be used to search libraries to identify an unknown protein. If this is insufficient, some sequence information on the peptides can be obtained by tandem MS (see below).

Peptides often produce ions with two to four charges. Although quadrupoles are normally operated at unit resolution, sufficient to resolve peaks differing by one m/z , the resolution can be increased to separate the isotopic peaks of multiply charged ions. The spacing of these peaks allows the determination of the charge state directly (e.g. triply charged ions have isotopic peaks spaced by $0.33 m/z$). Quadrupoles have demonstrated

sufficient performance to resolve isotopic peaks of up to +4 ions in the range $m/z < 2000$. This is usually more than sufficient for peptide analysis. A higher mass range is required for LC-MS and this has pushed quadrupole performance to new limits. Current systems have an m/z range of 2000–4000.

Triple Quadrupole Mass Spectrometers (MS/MS)

In tandem mass spectrometry (MS/MS) a first mass analyser selects an ion from a mixture, the ion is fragmented by collision, and a second mass analyser produces a spectrum of the fragment ions. MS/MS is used to determine ion structure and to detect and quantify targeted compounds in complex mixtures.

MS/MS can be carried out with a triple quadrupole system such as that shown in **Figure 8**. A first mass analysing quadrupole, Q1 mass selects a 'precursor' ion from the ESI source. The ion enters the collision cell with energies typically 10–500 eV. Here collisions with a neutral gas such as N₂ or Ar at a pressure 10⁻⁴ to 10⁻² mbar transfer translational energy to the internal energy of the ion. It then undergoes unimolecular reaction to produce fragment or 'product' ions (collision-induced dissociation). Ions are confined to the collision cell by a quadrupole, Q2, operated with only a radio-frequency voltage between the poles. A broad range of ions with $q < 0.9$ have stable trajectories and are transmitted to the exit of the collision cell. They are then mass-analysed in quadrupole Q3. The system in **Figure 8** shows an additional quadrupole Q0. This also operates in RF only mode and acts as an ion guide to transport ions from the skimmer to the first mass analyser.

Early triple quadrupoles were unable to efficiently extract higher mass ions from Q2 and at the same time to attain unit resolution in Q3 because of high fragment ion energies. A solution to this problem was found when it was recognized that by increasing the pressure in the

collision cell, product ions have additional collisions with neutrals. This causes them to lose radial and axial kinetic energy, i.e. to 'cool', and to move to the centre of the RF quadrupole. They are then well within the acceptance of Q3 and the transmission increases. In addition, product ions emerge from Q2 with energies and energy spreads of only about 1 eV. With a modern triple quadrupole system, at least 50% of the precursor ions that are transmitted by Q1 can be converted to fragment ions that are transmitted through Q3 with unit resolution or better. Resolution of the isotopic peaks of up to +4 ions has been demonstrated (**Figure 9**). The high collision pressure also minimizes any ion focusing effects which could lead to variable transmission. Hexapole or octopole fields have also been used to confine ions in the collision region.

A triple quadrupole has many scan modes. In 'product ion' scans, Q1 mass-selects an ion from a mixture, it is fragmented in Q2 and a mass spectrum of product ions is obtained by scanning Q3. This scan mode is useful to obtain structural information of an ion such as sequence information of a peptide. In 'precursor ion' scans, Q3 is fixed on a particular m/z value and Q1 scans through all the ions produced by the source. This scan is useful to identify those ions in the source that contain a particular functional group. In 'neutral loss' scans, Q1 and Q3 scan together with a constant difference in m/z that corresponds to loss of a given neutral group. For example, if the loss corresponds to Cl₂ (70 amu), this scan could identify ions that contain two or more chlorine atoms such as polychlorinated dioxins. For targeted compound analysis, the system can be run in 'single reaction monitoring' mode. Here Q1 is fixed at the m/z of the precursor ion of a targeted compound and Q3 is set to a m/z value of a major fragment ion of that compound. There is a massive discrimination against other compounds. If still greater selectivity is required, multiple reaction monitoring can be done. Here Q1 is set to the m/z value of the precursor and Q3 'peak hops' to several (say four) m/z values of

fragments that come from the targeted compound. If the intensity ratios of the fragments are correct, the compound is identified. If there is an interference on one of the fragments, the remaining fragments can be used to identify and quantify the compound. The ability to independently scan Q_1 or Q_3 under computer control makes a triple quadrupole MS/MS system a flexible tool for trace analysis. It has become the workhorse for LC-MS/MS and GC-MS/MS analysis.

An example of the use of a triple quadrupole MS/MS system to identify a protein is given here. The enzyme telomerase rebuilds the ends of chromosomes (telomeres) when cells divide. It consists of one RNA and two protein subunits of molecular mass 43 kDa and 123 kDa. The 123 kDa protein was separated on a 2D gel, extracted and digested to produce a mixture of peptides. Q_1 of a triple quadrupole was scanned to produce a spectrum of all the peptides, shown in **Figure 10a**. To identify these peptides, Q_1 was set to transmit a 2 m/z mass window and tandem mass spectra were collected with a 0.2 m/z step size. The fragment ion spectrum of a doubly charged peptide at m/z 830.4 is shown in **Figure 10b**. The doubly charged peptide ion fragments to singly charged ions to give fragments with m/z greater than the precursor. This mass spectrum along with esterification of the peptide allowed unambiguous assignment of the amino acid sequence. The sequences of eight of the peptides in the mass spectrum were determined. These amino acid sequences were then used to make DNA probes that led to

identifying the gene containing the complete sequence of the protein. The total amount of protein available for this experiment was in the low picomole range.

ICP-MS

Another major application area for quadrupoles is in ICP-MS systems for trace element analysis. A schematic of a system is shown in **Figure 11**. This ion source is an induction plasma in argon at atmospheric pressure with a temperature of 5000–7000 K contained in a torch. Samples are introduced to the plasma as aerosols, usually solutions that are sprayed. At the high plasma temperature dissolved solutes are vaporized, atomized and ionized. Most elements of the Periodic Table are present in the plasma as singly charged atomic ions (the degree of ionization is typically 90% or more). The plasma expands through an orifice about 1 mm in diameter into a region at a pressure of a few mbar, and the centreline flow then passes through a skimmer into a region at a pressure of about 10^{-4} torr. In this region ions are extracted from the rarefied plasma, pass through ion lenses and then are mass-analysed in a quadrupole.

ICP-MS with a quadrupole gives simple mass spectra that are easy to interpret. **Figure 12** for example shows the mass spectrum at unit resolution of some transition metals at a concentration of 100 ng mL^{-1} . By scanning a quadrupole over the range $^7\text{Li}^+$ to $^{238}\text{U}^+$, over 70 elements can be determined in a 1 min scan.

Figure 10 (a) Mass spectrum of the peptides obtained from digesting the 123 kDa subunit of telomerase. Peptides were not separated by chromatography. Peptides that were sequenced fully or partially are marked by T or t, respectively. (b) Tandem mass spectrum of the peptide at m/z 830.4. Reproduced with permission of The American Association for the Advancement of Science from Lingner J, Hughes TR, Shevchenko A, Mann M, Lundbald V, and Cech TR (1997) *Science* 276: 561–567.

Alternatively the quadrupole can peak hop to selected isotopes or elements, to improve the duty cycle. Detection limits are typically in the 10 pg mL^{-1} region for elements in solution. Isotopic information is inherent in ICP-MS. With a quadrupole the precision on isotope ratios is typically 0.2% with a measurement time of a few minutes. This is insufficient for many geological dating applications but is more than adequate for many isotopic tracing experiments in nutrition and other studies. In addition, it greatly facilitates quantification of trace elements by isotope dilution.

Figure 12 Mass spectrum of transition metals each present at 100 ng mL^{-1} in solution. The peak at m/z 56 also includes a contribution from $^{40}\text{Ar}^{16}\text{O}^+$. Small peaks at m/z 63–68 indicate contamination by Cu and Zn at concentrations of few ng mL^{-1} .

Ideally the ICP would produce only singly charged atomic ions of each element. However, it also produces some molecular ions such as ArO^+ which interfere with $^{56}\text{Fe}^+$, or Ar_2^+ which interferes with $^{80}\text{Se}^+$. Such interferences are most common at $m/z < 80$. To separate these interferences requires a resolution that is beyond the capabilities of quadrupoles operated conventionally,

although the use of alternative stability regions is being investigated. The interferences are not prohibitive because in many cases an alternative isotope can be found that is free of interference. As with many applications it is the comparatively low cost and electronic control of quadrupoles that make them attractive for ICP-MS.

Symbols

a	constant
A	absorbance
A	absorptivity
b	sample thickness, path length
c, C	concentration
F	fluorescence intensity
I	intensity of transmitted radiation
I_o	intensity of incident radiation
R	reflectance
T	transmittance
ε	molar absorptivity
λ	wavelength
Φ_f	fluorescence quantum yield

Spectroscopic techniques are particularly useful for quantitation. They offer speed and great flexibility in instrumentation. UV spectrophotometry is widely used for quantitation using data at the maximum absorbance of a chromophore. Fluorescence spectrometry is also widely used for quantitation as it provides greater selectivity and sensitivity than UV spectrophotometry. The use of FT-IR spectrometry for quantitation is less common. The use of NIR for quantitation is an area of great activity and innovation. In addition, NMR spectroscopy can be used for quantitation. Here the criteria for success are very different from those for absorption or fluorescence spectroscopy. NMR quantitation is the subject of a separate article in this encyclopedia.

Quantitation can be carried out using either absorption or reflectance measurements and the laws governing these two types of measurements will be discussed first.

Absorption of Light

The absorption of light by a compound depends on its chromophore, the wavelength of the light and the thickness of the sample. Bouguer derived the relationship between absorption and the thickness of the sample. The integrated form of the equation is shown in eqn [1] where I_o is the intensity of the incident radiation and I the intensity of the transmitted radiation. The factor a related to the absorptivity of the chromophore and b is a measure

of the sample thickness.

$$\log(I_o/I) = ab \quad [1]$$

Beer's law states that the absorption of monochromatic radiation by a sample is proportional to the concentration of the sample. The law is defined by eqn [2] where a' is a constant and c is the concentration.

$$\log(I_o/I) = a'c \quad [2]$$

Equations [1] and [2] are combined to give the Bouguer–Beer law shown in eqn [3] where ε is the molar absorptivity, i.e. the absorbance of a one molar solution of the compound. Note that ε is specific for each compound at a particular wavelength.

$$\log(I_o/I) = \varepsilon bc \quad [3]$$

The term $\log(I_o/I)$ is the absorbance, A , of the sample and eqn [3] is presented more simply in eqn [4], often referred to as Beer's law.

$$A = \varepsilon bc \quad [4]$$

Spectrophotometers measure the ratio of the intensity of the incident and transmitted radiation, which is known as the transmittance, T .

$$T = I/I_o \quad [5]$$

Absorbance is then related to transmittance as shown in eqn [6].

$$A = -\log T \quad [6]$$

Logarithms to the base 10 are usually used.

Reflection of Radiation

The use of reflection techniques is becoming common for quantitation. Taking measurements from the surface of a sample avoids the need for sample preparation and thus provides a very rapid method of analysis. One drawback of the use of reflectance measurements is that it is necessary to assume that the surface is representative of the sample as a whole. Reflectance measurements are commonly used in the NIR and FT-IR regions.

In reflectance measurements, $\log(1/R)$, where R is the reflectance of the sample, is proportional to concentration.

The proportionality constant is not as universal as in absorption. The constant will depend on factors such as the particle size of the sample and the moisture. The constant is thus unique for each sample and this makes quantitation using reflectance techniques very challenging.

Fluorescence

Fluorescence quantitation can be described by eqn [7]

$$F = (I_o)(\Phi_f)(1 - e^{-\epsilon bc}) \quad [7]$$

where F is the fluorescence intensity of the sample and I_o is the intensity of the incident light and Φ_f is the fluorescence quantum yield. The quantity $1 - e^{-\epsilon bc}$ derives from Beer's law, eqn [4], and relates to the fraction of light absorbed by the fluorescing species. Equation [7] can be expanded to eqn [8]

$$F = I_o \Phi_f \left(1 - \left[1 - \epsilon bc + \frac{(-\epsilon bc)^2}{2} - \frac{(-\epsilon bc)^3}{3} + \dots \right] \right) \quad [8]$$

At low concentrations with absorbance less than ~ 0.05 , eqn [8] can be reduced to eqn [9] and fluorescence is linearly related to concentration.

$$F = I_o \Phi_f \epsilon bc \quad [9]$$

The approximations made to derive this equation must be remembered and at high concentrations fluorescence will not vary linearly with concentration and a curved calibration graph will be obtained.

Quantitative Techniques

Data at a Single Wavelength

The simplest method of quantitation is to use data from a single wavelength. Ideally measurements should be taken at the wavelength of an absorption maximum because this avoids errors due to differences in wavelength calibration. This method of quantitation is usually used for absorption measurements rather than reflectance techniques which tend to require data from more than one wavelength. The absorbance of a solution of known concentration, the standard, is measured and compared to the absorbance of the sample whose concentration needs to be determined. Thus, if A_{sam} is the absorbance of the sample, A_{std} is the absorbance of the standard and C_{std} is the concentration of the standard the concentration of the sample, C_{sam} is given in eqn [10].

$$C_{\text{sam}} = A_{\text{sam}} \times C_{\text{std}} / A_{\text{std}} \quad [10]$$

Two standards should be prepared and the responses compared to ensure they have been prepared correctly. Typically, the two responses should agree within 1 per cent. The mean response from the two standards can then be used to predict the concentration of the samples.

If the concentration of the samples varies over a wide range, a calibration curve, constructed from standards of varying concentration, can be used. The responses of each standard should be checked to ensure that they agree and the regression coefficient of the line should be close to 1.

Often the molar absorptivity of the compound under investigation is so well characterized that the use of a standard is not necessary and published values of the absorbance of a 1 per cent solution in a 1 cm cell, A_1^1 , can be used. The use of A_1^1 values is particularly common in the pharmaceutical industry.

The drawback of using data at one wavelength is that the wavelength may not be specific for the compound of interest. The sample may contain other compounds that absorb at the same wavelength and interfere with the measurement. Thus quantitation using data at a single wavelength is limited to solutions of simple compounds. The technique is most commonly used in the ultraviolet and visible regions of the spectrum.

Derivative Spectroscopy

Derivative spectroscopy is useful in quantitative analysis both as a quantitative technique in its own right and for preprocessing data prior to analysis by some of the chemometric techniques described below.

A common problem in spectroscopic quantitation is that the band may overlap with a broad interfering band. The interfering band may arise from the sample matrix and give a sloping baseline making quantitation difficult. This is illustrated in **Figure 1** where the left-hand spectrum shows a band on a sloping baseline. The first derivative removes the sloping baseline provided it is linear. First derivative spectra are not always ideal for quantitation and often a second derivative spectrum, shown on the right of **Figure 1**, is used. The second derivative will remove any baseline curvature provided it can be fitted to a quadratic equation with respect to wavelength.

A first derivative spectrum is found by differentiating the absorbance spectrum and shows the rate of change of the slope of the absorbance spectrum. The derivative spectrum is found by calculating $dA/d\lambda$, where A is the absorbance and λ is the wavelength.

Derivative spectra are normally calculated off-line on the digital spectral data. The use of the Savitzky-Golay routine for calculating smoothed derivatives is common but other methods are available. Instrumental parameters need to be optimized to obtain successful derivatives. In

Figure 1 Left: A typical absorption band; Centre: The first derivative of the absorption band; Right: The second derivative of the absorption band.

particular, the data interval used to record the spectrum, the scan speed and the interval used to calculate the derivative need to be optimized.

The spectrum must first be scanned using a suitable data interval. If the data interval is too large then vital high frequency features will be smoothed out when the spectrum is recorded and the power of derivative spectroscopy will be lost. For derivative work it is usually best to choose a relatively small data interval to scan the spectrum. Any noise recorded by the small interval can be smoothed in the calculation of the derivative by varying the derivative interval. The interval used for the calculation of the derivative will influence the spectrum. Some trial and error may be necessary to find the correct interval.

Derivatives for Quantitation

When Beer's law, eqn [4], is differentiated with respect to wavelength only ε , the molar absorptivity, will vary with wavelength. The concentration C and the path length b are constant. The first derivative is given in eqn [11].

$$\frac{dA}{d\lambda} = \frac{d\varepsilon}{d\lambda} Cb \quad [11]$$

The derivative amplitude, $dA/d\lambda$, will be proportional to concentration and can be used for quantitation. Differentiating the first derivative spectrum forms derivative spectra of higher order. The second and fourth order derivatives are generally used for quantitation. **Figure 1** shows first and second derivative spectra.

Derivative spectroscopy can be used for analysis of mixtures when two components have different bandwidths. The technique is particularly useful when one compound has a spectrum with sharp features and another component

has broad features. The sharp band can be emphasised at the expense of the broad band.

The use of derivative spectroscopy for direct quantitation is limited to compounds where the spectra show major differences. Quantitation can be carried out using data at single wavelengths or the whole spectrum can be used in some of the chemometric techniques described later.

Chemometric Techniques

Chemometric techniques have found widespread use in spectroscopic quantitation. The techniques are used when a single wavelength, which is specific for the compound of interest, cannot be found. Wavelengths have to be found where the species contributing to the spectrum have different absorption or reflectance. Mathematical approaches can then be used to unravel the contribution to the spectrum of the compounds of interest and hence deduce their contribution.

In a mixture of compounds the absorbance at a particular wavelength can be considered to arise from a linear combination of the absorbances from the individual components. If two components contribute to the spectrum we can expand Beer's law to reflect the individual contribution of each component as shown in eqn [12], where the subscripts 1 and 2 refer to the two components.

$$A = \varepsilon_1 b c_1 + \varepsilon_2 b c_2 \quad [12]$$

If we know the molar absorptivities, ε_1 and ε_2 , for each component and the path length, b , eqn [12] still cannot be solved for the concentrations, c_1 and c_2 , because there are too many variables. To solve for the concentrations of the two components it is necessary to have data at two wavelengths where the molar absorptivities of the two

components are different both from each other at both wavelengths. Two simultaneous equations can be constructed and solved for the two concentrations. If more than two components contribute to the spectrum, it is necessary to find extra wavelengths for each component where the molar absorptivities differ. Analogous equations can be written for reflectance measurements.

Rather than use simultaneous equations it is usual to resort to regression techniques. These fall into three main techniques such as multiple linear regression (MLR), principal component regression (PCR) and partial least squares (PLS). All three techniques have found widespread use in spectroscopic quantitation using both absorption and reflectance techniques.

Multiple linear regression requires careful choice of wavelengths to find a quantitation model that is robust. PCR and PLS overcome problems of wavelength selection by using the full spectrum. PLS is often considered to give superior results to PCR. Full discussions of the algorithms and details of how to apply the techniques can be found in the monographs on chemometrics listed under Further Reading.

Multiple Linear Regression

Multiple linear regression can be used to solve for the constants in eqn [13], which can be described as a general equation for any n components as shown in eqn [13].

$$A = \varepsilon_1 bc_1 + \varepsilon_2 bc_2 + \varepsilon_1 bc_1 + \varepsilon_3 bc_3 + \cdots + \varepsilon_n bc_n \quad [13]$$

Matrix algebra is used to simplify the mathematics and eqn [13] is described in matrix terms in eqn [14]. This is a general equation for any spectroscopic data, be it absorption, reflection or derivative data.

$$\mathbf{y} = \mathbf{X}\mathbf{b} + \mathbf{e} \quad [14]$$

The vector, $\mathbf{y}$, is a column vector of spectroscopic data for each sample at one wavelength. The matrix $\mathbf{X}$ contains the concentrations of the samples. If an intercept is included in the model, then the first column of $\mathbf{X}$ must be a column of 1s. The vector $\mathbf{e}$ is a column of residuals associated with lack of fit in the model. The vector $\mathbf{e}$ contains the errors that are minimized in the regression analysis.

The matrix solution for $\mathbf{b}$ in eqn [14] is given in eqn [15].

$$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \quad [15]$$

where $\mathbf{X}'$ is the transpose of $\mathbf{X}$ and $(\mathbf{X}'\mathbf{X})^{-1}$ is the inverse of the covariance matrix $\mathbf{X}'\mathbf{X}$. The inversion of the

covariance matrix is not always possible and this is the main drawback to MLR.

The practical steps involved in MLR are as follows. A set of calibration samples is selected and the concentration of the component of interest is determined by a reference technique. The spectroscopic data and the concentrations from the reference technique are fed into eqn [15] to give an equation that can be used to predict the concentration of the component in further samples.

MLR can result in simple equations that can be used for quantitation. For example, the constituents of food, such as moisture and fat, can be determined using spectroscopic data at a few NIR wavelengths. The disadvantages of MLR are that it requires the operator to select the wavelengths. The selection of inappropriate wavelengths can result in poor models that are mathematically unstable.

PCR and PLS

PCR and PLS were developed to overcome the limitations of MLR. They use all the spectral data and so avoid the need for wavelength selection. PCR is essentially a mathematically more robust way of carrying out MLR. The regression is performed on the principal components of the data set. The principal components are determined from the data set with the specific aim that they will provide robust models. The principal components are linear combinations of the original measurements such that the first component explains the most variance in the data and subsequent components, all orthogonal, explain decreasing amounts of data variance.

The data set is broken down into loadings, which are analogous to abstract spectra, and scores, which describe the amount of each loading associated with each sample and are similar to abstract concentrations. Some of the loading spectra will describe noise or minor components and will not be relevant to the model and can be rejected. Determining which principal components can be rejected affects the robustness of the model.

A set of calibration samples is identified and the concentration of the components of interest is determined by a reference technique. The spectra are assembled into a data matrix often known as the calibration matrix. The data matrix is decomposed into the product of a score and a loading matrix using principal component analysis. Irrelevant principal components describing noise are rejected, typically those components of higher index.

Multiple linear regression is then used to relate the scores matrix to the matrix of concentrations determined by the reference technique.

The model is then complete and can be used to predict the concentration of the components of samples.

The calibration set can be used many times provided the samples in the set have been chosen carefully. A good calibration set of samples will contain samples that arise from every source of variation likely to be encountered in further samples that the method will be used to quantify.

PCR takes no account of the concentration of the samples in the calibration set when finding the principal components and this has been considered a drawback. PLS was developed to use the concentration data when developing the mathematical model. PLS is thus claimed to be superior to PCR.

The practical application of PCR and PLS is very similar. Samples are selected for the calibration set and a reference technique is used to determine the concentration of the component or components of interest. The spectra and concentrations then allow a calibration model to be set up for predictions of further concentrations.

Pretreatment of the spectroscopic data is usually carried out to improve the model. A first derivative can be applied to remove sloping backgrounds and offset errors. This is a very common method of pretreating NIR spectra. The data can be centred about its mean. Routines are available to smooth the data and remove spectroscopic scatter.

Once a set of calibration spectra have been set up the use of data pretreatment can be examined to find the optimum pretreatment. Similarly PCR and PLS can be compared to see which gives the best results.

Validation

Whatever method is chosen to perform the quantitation, whether a simple, single wavelength assay or a complex chemometric method, the method should be validated to ensure it produces meaningful data. Before the method can be validated, the exact procedure should be documented so that the final method is used in the validation experiments.

Validation should look at the following parameters:

- Linearity
- Specificity
- Accuracy
- Precision
- Robustness

Linearity

The linearity of the method should be checked over and beyond the likely operating range of the method. Typically six concentrations of the standard solution over the range 25 to 150% of the normal working concentration should be examined. A graph of absorbance against concentration can then be constructed. The intercept of

the line should be examined to see how close to the origin the line crosses the X axis. A large intercept will indicate an offset error in the method or nonlinearity.

Specificity

The specificity of the method can be checked by running a sample without the compound of interest, if one is available. The method can also be compared with other methods of known specificity. The acceptable limit of interference from the sample matrix will vary with the sample and the use of the results from the analysis. Typically, an interference of $<2\%$ would be expected but higher values can often be tolerated.

Accuracy

The accuracy of the method is a measure of how close to the true value the results from the method are. Accuracy is usually checked by preparing samples spiked with known amounts of the component of interest. The accuracy should be examined over a range that extends beyond the range of samples the method is likely to analyse. If the method is designed to measure samples at 100% of expected strength then it would be useful to check the accuracy at that value and at 80% and 120% of the expected strength. Results from the accuracy experiments should normally agree to within 2% of the true value.

When samples cannot be spiked with the component of interest then comparisons with a reference technique should be carried out.

Precision

Precision is a measure of the spread of results from a method. Precision can be broken down into subsections. The first measurement of precision relates to how repeatable the spectroscopic measurements are. Taking ten readings and looking at the coefficient of variation can assess the repeatability of the spectroscopic measurement. Normally the coefficient of variation should be $<2\%$.

The repeatability of the sample and standard preparation can be assessed by preparing ten samples and standards from the sample source and examining the coefficient of variation of the response.

Depending on where the method is used the precision of different operators, equipment and laboratories should also be examined. Interlaboratory precision can be determined by having different laboratories analyse the same sample.

Robustness

The robustness of the method should be examined by stressing the method parameters. Thus the effects of slight changes in wavelength, spectroscopic settings, sample preparation, etc. can be varied to see if any of the values are critical. The most effective way of doing this is to use experimental design so that parameters are varied in a planned way and statistics and response surfaces can be used to evaluate the outcome of the results.

TOCSY	total correlation spectroscopy

Introduction

^1H and ^{13}C NMR spectroscopy is routinely used for the elucidation of structures of newly synthesized compounds, natural products, and semisynthesized compounds. Utilizing two-dimensional techniques such as correlation spectroscopy (COSY), heteronuclear multiple bond correlation (HMBC), heteronuclear single quantum coherence (HSQC), total correlation spectroscopy (TOCSY), nuclear Overhauser effect spectroscopy (NOESY), and rotating frame Overhauser effect spectroscopy (ROESY) experiments, the constitution, configuration, and conformation of small molecules, polymers, peptides, proteins, sugars, or nucleotides can be elucidated. Additionally, ^{19}F , ^{15}N , and ^{31}P NMR can be employed in structure determination.

According to the definition of the CCQM (Comité Consultatif pour la Quantité de Matière), NMR spectroscopy is a primary method of measurement; therefore, it can also be used for quantification purposes. NMR in combination with chiral additives, for example, chiral solvating agents or chiral shift reagents, is very often applied in organic asymmetric synthesis, especially for evaluating the enantiomeric excess of a chiral compound. However, as early as 1963, Hollis had performed the first quantitative NMR (qNMR) measurement on a mixture

of drugs, demonstrating the applicability of ^1H or ^{13}C NMR spectroscopy for the identification and quality assessment of drugs and excipients.

qNMR was not accepted for a long time due to its low sensitivity and precision of quantification. Using an NMR spectrometer of medium field strength (≥ 300 MHz for ^1H observation), gradient shimming techniques, and inverse and cryo probes, in addition to maximizing the concentration of a sample and minimizing the solvent/analyte ratio (e.g., microcoil technology), and a high number of scans, pure substances and by-products as well as mixtures of substances can be precisely evaluated in a nanomolar range of concentration. Nowadays, quantitative ^1H , ^{13}C , ^{31}P , and ^{19}F NMR in liquids is used routinely, for example, in pharmacy, agriculture, and material science, where assay or content determination of substances (and impurities) is the key issue.

In this article, the methods of qNMR will be described by means of pharmaceutical examples. In the pharmaceutical field, qNMR can be used for identification of a drug or excipient, for determination of the level of impurities (i.e., related substances), the content of residual solvents, and the isomeric composition, that is, the ratio of diastereomers and the ratio of enantiomers (enantiomeric excess (ee)), and for an assay of single drugs or drug composition.

Basics of qNMR

The intensity of an NMR signal is given by the area under the specific signal. This area is calculated by modern spectrometer software. The intensity I of a signal is directly proportional to the number of nuclei N evoking the signal. Owing to this relation, the intensities of NMR signals can be used for quantitative purposes:

$$I = K_s N \quad [1]$$

with K_s being a spectrometer constant.

One prerequisite for quantitative measurements is the purity of the NMR signal considered for quantification. Application of homo- and heteronuclear correlation spectroscopic techniques can help to ensure the signal purity. However, ^{13}C and ^{29}Si satellites as well as rotation sidebands may also interfere with the NMR signal. The area of these signals has to be subtracted in case of quantification or the experimental conditions have to be changed to avoid the interference, for example, no

rotation of the sample for deletion of the sidebands or the corresponding decoupling experiments.

Another prerequisite is the constancy of K_s for all resonance lines in the spectrum, which is given when a number of criteria for the acquisition parameters are considered:

- The pulse excitation must be uniform for the spectral width of interest, which requires short pulses (typically 10 μ s). In this case, ^1H NMR spectra can be acquired quantitatively. However, spectra of heavier nuclei such as ^{19}F or ^{31}P with larger chemical shift ranges may suffer from intensity distortions, particularly if measured at very high magnetic fields.
- The repetition time τ (often called recycling time) depends on the longest longitudinal relaxation time T_1 of the signals considered. The T_1 relaxation is described by

$$M_z = M_0(1 - e^{-\tau/T_1}) \quad [2]$$

where M_z and M_0 are the magnetization values along the z -axis (response factor) after waiting time τ and at thermal equilibrium, respectively. Routine measurements are done by choosing $\tau = 5 \times T_1$. Hence, 99.3% of the equilibrium magnetization (signal) is measured. In the case of nuclei with very long T_1 values, that is, ^{13}C , ^{29}Si , or ^{31}P , paramagnetic relaxation reagents (such as $\text{Cr}(\text{acac})_3$) can be added for reduction of T_1 .

- Heteronuclear NMR experiments of other nuclei than ^1H such as ^{13}C or ^{19}F with simultaneous ^1H broadband decoupling create inherent intensity distortions by the nuclear Overhauser enhancement (NOE) effect. This NOE effect on the spectrometer constant K_s can be described by

$$K_s = K_0(1 + \eta) \left(\frac{1 - e^{-\tau/T_1}}{1 - \cos \alpha \cdot e^{-\tau/T_1}} \right) \sin \alpha \quad [3]$$

where K_0 is a constant instrumental factor, η is the NOE factor, and α is the flip angle of the excitation pulse. To suppress such intensity distortions below 1%, the following rules must be fulfilled: (1) ^1H decoupling is applied only during the signal acquisition time to minimize η (inverse-gated technique), (2) the repetition must be set to five to seven times T_1 , and (3) a 90° pulse should be used for the excitation. The T_1 relaxation time of all hydrogen atoms can be determined using an inversion-recovery pulse sequence.

- The required acquisition time t_{aq} depends on the smallest line width in the spectrum, and truncation of the NMR signal in the time domain (free induction decay) must be avoided. Usually, the signal should decay completely half way through the acquisition period. In this case, enough data points will describe

the NMR lines (at least five data points above the half height of the signal) and the integration procedure does not cause artificial distortions.

- The accuracy of the integration procedure depends on the appropriate signal-to-noise ratio (S/N). For a precision of $<1\%$, S/N ratios of 250:1 (^1H), 300:1 (^{19}F), and 600:1 (^{31}P) are recommended.

Besides these mostly robust acquisition parameters, the precision of the integrals along with the accuracy of quantification depends on processing parameters and the integration:

- Choice of the window function: a larger line broadening (LB) factor improves the S/N, but simultaneously complicates the integration in the case of a close neighbor signal.
- Zero filling: This is the addition of data points that equals zero. This procedure increases the digital resolution. However, a factor of more than 2 should not be used.
- Line shape considerations, along with the integration that is influenced by phase, baseline, and drift corrections, which can be done automatically and/or manually: especially in the latter case, the integration will vary from one operator to the other, which cannot be avoided because the software routines cannot solve the problems. Additionally, the integration limits should be set to the range of 64 times the full width at half signal height (fwhh) to assure that $>99\%$ of the whole signal intensity (the signal is a Lorentzian line) is obtained.

A typical parameter setup for quantitative purposes is given in **Table 1**, taken from Malz in *NMR Spectroscopy in Pharmaceutical Analysis* (see Further Reading).

Quantitative NMR Spectroscopy

As explained earlier, the signal intensity I_1 is a true measure of the number of nuclei (N_1) for the respective signal under the conditions of essentially complete relaxation between the scans. Since the constant K_s includes fundamental constants, properties of the receiver parameter and sample, it can be disregarded when signal intensities are compared. The comparison results in the direct relation between the number of nuclei in the compared structure groups X and Y :

$$\frac{I_X}{I_Y} = \frac{N_Y}{N_X} \quad [4]$$

The numbers (N_i) of nuclei belonging to different structure groups of one molecule are small integers, and the values measured are rounded to the closest integer number.

Table 1 Parameters to be considered for quantitative purposes and their exemplified values (for 300 and 400 MHz instruments)

¹ H NMR parameters	Abbreviations	Value
90° pulse strength	PI1	Instrument specific
90° pulse length	P1	Instrument specific
Sample rotation		No
Measurement temperature	TE	300 K
Frequency of excitation	O1	Middle of spectrum
Pulse angle		30°
Preacquisition delay	DE	6 μs
Acquisition time	AQ	5.9 s
Relaxation delay	D1	≥ (7/3) × longest T ₁
Spectrum width	SW	14 ppm
Filter width	FW	≥ 20 ppm
Number of FID points	TD	64k
Number of scans	NS	Dependent on the S/N reached
Signal-to-noise ratio	S/N	≥ 150
Line broadening (em)	LB	0.3 Hz
Number of frequency spectrum points	SI	64k

Abbreviations according to Bruker Biospin.

Relative Method

Since the intensities of signals, arising from each component in a mixture, are related to each other (by small integer numbers), the relative molar amounts of these components can be assessed by the comparison of the normalized intensities of the corresponding signals. The molar ratio of two components can be calculated from

$$\frac{n_X}{n_Y} = \frac{I_X}{I_Y} \frac{N_Y}{N_X} \quad [5]$$

The determination is valid only in cases where the structures of the molecules *X* and *Y* are known. Hence, the amount percent of a compound *X* in a mixture of *m* components is given by

$$\frac{n_X}{\sum_{i=1}^m n_i} = \frac{I_X/N_X}{\sum_{i=1}^m I_i/N_i} \times 100\% \quad [6]$$

The signal of the solvent of the mixture has to be disregarded. Thus, the relative qNMR method can be used in the quantification of ratios of diastereomers or

enantiomers. This is demonstrated for fluvoxamine, an antidepressant drug whose activity resides with the *E* diastereomer. The relevant structural formula and the ¹H NMR spectrum are given in **Figure 1(a)**.

To ensure complete relaxation of the signals between the scans, the *T*₁ relaxation time was determined. Hence, the delay was incremented from 0.01 to 10 s, as shown in **Figure 1(b)**. Using the inversion-recovery sequence, the *T*₁ relaxation time is roughly given by 1.44 times the indicated delay at which the intensity of a signal is zero. Using the algorithms provided by the spectrometer software, the *T*₁ relaxation time of the signal at 2.9 ppm was determined to be 0.562 s and that of the signal at 4.2 ppm to be 0.932 s. To reach the aforementioned recovery of the *z*-magnetization of more than 99.3%, a pulse repetition period of five times the longest *T*₁ time, that is, 5 s, was applied.

To determine the limit of detection (LOD) and the limit of quantification (LOQ) of the *Z*-isomer, the standard solution was diluted forming a geometrical series. After optimization of the experimental conditions, three spectra of every aliquot were measured and each spectrum was three times manually integrated, giving a linear regression curve with $y = 1.042x + 0.00$ and $R^2 = 0.998$. The *Z*-isomer of fluvoxamine had an LOQ of 0.2%, which was obtained by integrating the signals of the OCH₂ hydrogens between $\delta = 4.2$ and 4.5 ppm. In contrast, the chromatographic method given in the British Pharmacopoeia is able to limit the *Z*-isomer to 0.5% only.

Absolute Method

Absolute methods have two options: the normalization method and the use of an internal or external standard.

Normalization method

The normalization method can be applied to determine the relative proportion of components in a mixture, the degree of substitution, for example, in a structurally modified polymer, or the amount of contaminants by comparing the relative intensities of the signals present (also called the 100% method). There are a few prerequisites: (1) all impurities to be detected must be seen in the spectrum, for example, inorganic impurities such as NaCl cannot be observed; (2) the structures of all components are known and their signals in the spectrum can be assigned; and (3) there is no overlap of signals or the problem of partially overlapping signals can be solved by calculation.

In the case where the contaminant to be determined is structurally not exactly determined (e.g., a polymer of varying molecular mass), the addition of known amounts of this material to the sample will allow the establishment of a calibration curve.

Figure 1 (a) 400 MHz ^1H NMR spectrum of a mixture of *E*- and *Z*-fluoxetine in CD_3OD (15.5 mg ml^{-1}). (b) Stacked T_1 plot of *E*-fluoxetine (inversion-recovery pulse sequence). On the left-hand side, the time delay is given.

Internal standard method

The main component P_X can be calculated directly from the NMR spectra using a standard of known content P_{Std} :

$$P_X = \frac{I_X}{I_{\text{Std}}} \frac{N_{\text{Std}}}{N_X} \frac{M_X}{M_{\text{Std}}} \frac{m_{\text{Std}}}{m} \times P_{\text{Std}} \quad [7]$$

with M_X and M_{Std} being the molar masses of analyte and standard, m and m_{Std} the weights of sample and standard, and P_X and P_{Std} the contents of analyte and standard, respectively. The internal standard has to be chosen carefully. It has to be well defined and of high purity, stable and inert, nonhygroscopic, completely soluble in

the solvent used for the analyte, and inexpensive, and it should have a low number of signals with no overlap with the signal of the analyte considered. It is advantageous that the intensity of the analyte signals of interest and that of the standard are almost equal, and a singlet is preferable. Additionally, the standard should have a short T_1 time, at least in the same range as the analyte. Typical symmetrical standards such as maleic acid exhibit a long relaxation time and have to be handled carefully.

In the case where the contamination of the analyte with the standard has to be prevented, an external standard can be used in a concentric tube (putting a capillary, filled with the dissolved standard, inside the analyte NMR tube) or in a separate precision tube (using two NMR tubes filled with the analyte and the standard solutions, respectively). In both cases, the analyte and the standard have to be dissolved in the same solvent and the volumes of the tubes (capillary) have to be calibrated.

Alternatively, the ERETIC (electronic reference to access *in vivo* concentrations) technique, first reported by Akoka in 1998, can be applied: an electronic reference signal is fed into the resonance circuit of the probe during the acquisition time using a free coil in the probe (heteronuclear channel). Amplitude, full-width at half height (fwhh), and frequency (chemical shift position) can be set by the operator. Hence, the electronic signal can be placed in a free spectral range avoiding superposition with the analyte signals. ERETIC can be used in 1D and 2D ^1H and ^{13}C NMR, in liquid- and solid-state qNMR, and in magnetic resonance imaging (MRI).

Specificity and Selectivity

The main prerequisite for qNMR is that the signal chosen for quantification should be unambiguously assigned to a structural group of the analyte. It is advantageous to look at a singlet or at least a multiplet of only a few lines, and the fwhh should be ~ 1 Hz only. Additionally, the signal observed should not interfere with signals of other substances (impurities).

Specificity is defined as the ability to assess unambiguously the analyte of interest in the presence of other components, and selectivity is the ability to determine the analyte of interest in a complex mixture without interference from other components in the mixture. This can be checked, for example, by homo- and heteronuclear correlation spectroscopic experiments or by comparison of the integrals of the different components of the analysis mixture.

To achieve the selectivity, overlapping signals might be separated by changing the pH value of the solution, the temperature, the solvent (or solvent mixtures), or the analyte concentration. Homonuclear decoupling might also be a solution to the problem of overlapping signals.

Codergocrine mesylate is a mixture of the methane-sulfonate salts of three dihydroergopeptide alkaloids, namely dihydroergocornine (Cor), dihydroergocristine (Cr), and dihydroergocryptine and its regioisomers, in a ratio of 1:1:1. They differ only in the structure of the side chain R at C5' (see **Figure 2**). Use of different solvents of different polarity or solvent mixtures resulted in a complete separation of the signals of H5' and a precise quantification was achieved by means of a benzene-DMSO mixture. The results were in agreement with those obtained by the HPLC method reported in the European Pharmacopoeia 6.0.

Applications

After validation with regard to linearity, robustness, accuracy, and precision, qNMR can be applied in the analysis of drugs, agrochemicals, and food (impurity profiling, determination of the content); the characterization of vaccines and polymers (e.g., excipients); and the metabolic profiling of drugs, using ^1H , ^{13}C , ^{19}F , ^{15}N , or ^{31}P NMR spectroscopy. Multivariate analysis may be applied for inspection of high number of analyses or complex mixtures. Hyphenation with liquid chromatography and capillary electrophoresis can further help in quantification of complex mixtures, occurring, for example, in biofluids.

Typical Example of Impurity Profiling: Unfractionated Heparin

In 2007, a number of people in the United States died from treatment with unfractionated heparin, which is a natural preparation containing the calcium or sodium salt of a sulfated glucosaminoglycan and which is widely used in dialysis therapy. NMR spectroscopic investigations revealed that a synthetic oversulfated chondroitin sulfate (OSCS) as a contaminant was responsible for the observed anaphylactoid reactions and deaths. Additionally, dermatan sulfate (DS) and chondroitin sulfate A and C (CS A/C) (**Figure 3**) were identified at up to 30% in the many heparin batches.

qNMR with instruments operating at ≥ 400 MHz can be used for the quality assurance of heparin batches by means of the inspection of the acetyl region of the heparin spectrum. For ^1H NMR spectra, about 25 mg of heparin was dissolved in 750 μL D_2O . Using 128 scans collected into 64k data points over a spectral width of ~ 4800 Hz with the transmitter offset at 5.00 ppm, an acquisition time of 6.84 s, followed by a relaxation delay of 1 s (total pulse recycle time of 7.84 s) to ensure full T_1 relaxation of the *N*-acetyl signal of heparin and its impurities, the contaminant OSCS could be easily quantified at a level less than 0.1% (see **Figure 3**).

Figure 2 (a) Structural formula and partial 400 MHz ^1H NMR spectra of the H5' region of codergocrine mesylate, ordered by improved signal separations, for the following solvents: (b) DMSO- d_6 (left) and methanol- d_4 (right). (c) Optimal signal separation is achieved with benzene- d_6 :DMSO- d_6 in a ratio of 10:1 (v/v).

Moreover, information about the composition of the heparin can be extracted by looking at the more complicated fingerprint part of the spectrum between 3.3 and 5.5 ppm. However, inspection of this part needs an elevation of the measuring temperature to at least 315 K in

order to shift the residual water signal out of this region. The individual spectra of the heparin components shown in **Figure 3** clearly demonstrate the differences. The contaminated batch contains heparin and OSCS, but neither chondroitin sulfate A and C nor dermatan sulfate.

Figure 3 (a) Structural formulae of the different components of heparin: (i) OSCS, (ii) heparin, (iii) dermatan sulfate (DS), and (iv) chondroitin sulfate A and C (CS A/C). R marks the sulfated moiety, as for chondroitin sulfate C the residual group R' is sulfated. For OSCS, R¹-R⁴ label possibly sulfated moieties. (b) Acetyl region of the 400 MHz ¹H NMR spectrum of the different components of heparin: CS A/C, OSCS, DS, heparin, and a contaminated heparin sample. Chemical shifts of the components are as follows: CS A/C, $\delta = 2.04$ ppm; heparin, $\delta = 2.05$ ppm; DS, $\delta = 2.08$ ppm; and OSCS, $\delta = 2.15$ ppm. (c) 400 MHz ¹H NMR spectra of the fingerprint region of the different components of heparin. (d) Determination of the LOD by means of 400 MHz ¹H NMR spectroscopy. (e) ¹H NMR spectrum of a typical contaminated sample.

Additionally, methanol and ethanol signals can be found, which are "imported" by the last production step – precipitation of the heparin using methanol and/or ethanol.

The heparin example demonstrates nicely the possibilities that qNMR can provide: evaluation of the composition of unfractionated heparin including the impurity OSCS and determination of the residual solvent. Consequently, the European Pharmacopoeia and the competent authorities have prescribed qNMR for quality assurance of heparin.

Symbols

B_0	static magnetic field
B_1	alternating magnetic field
D	self-diffusion coefficient
g_1	gradient amplitude
I_+ and I_-	raising and lowering operators
p_i	coherence order
r	coil radius
S	signal
T_1	longitudinal relaxation time
T_2	transverse relaxation time
α	flip angle
γ	gyromagnetic ratio
δ	chemical shift
Δ	diffusion interval
θ	angle of nutation
ν_0	resonance frequency
ν_r	transmitter frequency
ρ	spin density
σ	shielding coefficient
ω_r	rotating frame angular velocity

Any NMR experiment requires two magnetic fields, a static one denoted by B_0 which serves to polarize the nuclear spins (or to create two distinct energy levels in the case of spins $\frac{1}{2}$) and an alternating magnetic field B_1 , also called the radiofrequency field (RF field) because of its usual frequency domain, whose purpose is to induce transitions. It can be mentioned that, in pulse NMR experiments, the RF field serves merely to rotate nuclear magnetization, or, in a more general way, to rotate spin operators involved in the description of the various populations or coherences that may exist or appear in the course of the experiment. In fact, these rotations occur in the so-called rotating frame, that is a frame which rotates at a constant angular velocity ($\omega_r = 2\pi\nu_r$, ν_r being the transmitter frequency) around the Z direction defined by

B_0 . We shall denote (x, y, z) as the rotating frame and (X, Y, Z) , with $Z \equiv z$, as the laboratory frame. In the rotating frame, the RF field is stationary and oriented along x, y or any axis in the (x, y) plane according to its phase. Finally, during receive operations, the rotating frame has still to be considered. This is due to the particular scheme usually employed in NMR that detects the signal, not at its own frequency ν_0 , but at a relative frequency $(\nu_0 - \nu_r)$ by means of appropriate devices (mixers). Moreover, by means of the so-called quadrature detection scheme, two signals can be acquired simultaneously: $\cos 2\pi(\nu_0 - \nu_r)t$ and $\sin 2\pi(\nu_0 - \nu_r)t$.

Most of the time, the experimentalist aims at uniform magnetic fields, either B_0 or B_1 . For the former, this need arises from the basic Larmor equation which provides the resonance frequency ν_0 :

$$\nu_0 = \frac{\gamma B_0}{2\pi}(1 - \sigma) \quad [1]$$

(γ is the gyromagnetic ratio and σ the shielding coefficient, which determines the chemical shift of the considered nucleus). Thus a uniform B_0 field prevents line broadening or resonance spreading. For the latter, the need arises from the relation which provides the flip angle α (the angle by which a magnetization component or a spin operator rotates around the B_1 direction in the rotating frame) is

$$\alpha = \gamma B_1 \tau \quad [2]$$

(τ is the duration of the RF field application or more simply the duration of the RF pulse). A homogeneous B_1 field prevents a distribution of flip angles and, if the same coil is used for signal detection, a nonuniform receptivity by virtue of the reciprocity principle.

However, very early on it was recognized that some advantages may be drawn from using non-uniform magnetic fields. The simplest situation is a linear variation of the B_0 amplitude (B_0 still being oriented along Z)

with respect to a spatial direction, say X . Let g_0 be the (uniform) slope of this variation, leading to an equation indicating how B_0 varies with respect to X

$$B_0(X) = B_{00} + g_0 X \quad [3]$$

Combining eqns [1] and [3], it is apparent that the resonance frequency also depends linearly on X and therefore can provide information about any property which occurs that is spatially dependent. This simple feature led (1) to the capability of measuring self-diffusion coefficients, (2) to the various imaging methods, and (3) in a more subtle way, to the selection of coherence pathways.

Radiofrequency field gradients (RF gradients, or B_1 gradients) work in a different way (although strongly related) to B_0 gradients. In this case, it is the nutation frequency $\nu_1 = \gamma B_1 / 2\pi$, i.e. the frequency at which magnetization rotates in a plane perpendicular to B_1 (see eqn [2]), which is spatially dependent; in other words, spatial encoding occurs via nutation and not via precession. It will be shown in this article that virtually all experiments that can be carried out with B_0 gradients can also be considered with B_1 gradients, sometimes with clear advantages, but unfortunately with some inconveniences which make the two approaches rather complementary. A common feature to these two types of gradients is the ability to *defocus* nuclear magnetization. This means that if a gradient of sufficient strength is applied for a sufficient time, it is capable of spreading out in the relevant plane all elementary magnetization vectors of a homogeneous sample so that the net result is zero.

Creation of B_1 Gradients and Their Specificity with Respect to B_0 Gradients

The first problem of concern is the uniformity of gradients. As will be discussed below, gradient uniformity appears to be mandatory for imaging experiments, recommended for self-diffusion measurements, but not really necessary in pure spectroscopic applications (selection of coherences, solvent suppression, etc.). The best way for creating a uniform B_1 gradient is a flat coil which may comprise a single or several turns. For a circular single-turn coil, it can be shown that good uniformity is obtained in a region extending from $0.2r$ to $0.9r$ from the coil centre (r being the coil radius). The gradient strength is directly proportional to the B_1 field at the coil centre and thus depends on the coil quality factor and on the RF power it can hold. This is of course strongly related to the measurement frequency, low frequencies allowing stronger gradients. The state-of-the-art, as far as uniform gradients are concerned, corresponds to gradients up to 800 mT m^{-1} at a measurement frequency of 100 MHz (obtained with a two-turn coil). It must be borne in mind that the gradient efficiency is in any event weighted (or enhanced) by the gyromagnetic ratio of the observed nucleus. As an example, **Figure 1** shows the experimental B_1 distribution in a 2 mm diameter sample obtained with a two-turn flat coil of 15 mm and 11 mm diameters respectively. Anyhow, the production of a B_1 gradient makes sense only if a detection coil with uniform receptivity exists within the probe. Because, most of the time, the detection coil is tuned at the same frequency as the

Figure 1 Three-dimensional diagram demonstrating the excellent uniformity of an RF gradient created by a two-turn flat coil (respective diameters: 15 and 11 mm).

gradient coil, this poses a leakage problem between the two coils. Ideally, they should be orthogonal. Achieving this orthogonality, although requiring fine mechanical adjustments, proves to be feasible. However, creation of RF gradients in the two complementary directions is actually a challenge. Let X be the direction of the RF gradient created by the specific coil and let Y be the axis of the detection coil (Figure 2). It is conceivable that the inherent inhomogeneity of the detection coil affords a B_1 gradient in the Z direction (if, for instance, it is of the saddle-shape design), although uniformity is far from being warranted. What about a B_1 gradient in the Y direction? If one imagines the installation in the probe of a second gradient coil, identical to the first one and orthogonal to it, its axis would be collinear to the detection coil with evidently a full leakage. This solution cannot be obtained in practice at present and whenever RF gradients in the X and Y directions appear to be necessary, the best way for tackling this problem is to rely on a single coil and to rotate the sample. This is clearly a major drawback of B_1 gradients vs. B_0 gradients which can be created independently in the three spatial directions without perturbing the RF system. On the other hand, RF gradients offer some distinct advantages over B_0 gradients which are summarized in Table 1.

In a general way, two points in favour of B_1 gradients must be emphasized: (i) a simple instrumentation (at least much simpler than the one currently employed for B_0

Figure 2 Sketch of a probe possessing B_1 gradient capabilities. The single-turn coil serves for generating an RF gradient in the X spatial direction. The saddle coil (in principle electrically orthogonal to the latter) is used essentially for detection purposes. Possibly it can produce an RF gradient in the Z direction.

gradients); (ii) their double function, since they perform both spin excitation and spatial labelling. This latter feature may lead to a considerable simplification of experiments, usually requiring magnetic field gradients.

Self-diffusion measurements

In order to illustrate the above statement, let us consider the B_1 gradient experiment used for measuring self-diffusion coefficients. The classical method is the PFGSE (pulsed field gradient spin echo) experiment which involves two pulses of B_0 gradient on both sides of the 180° RF pulse in a spin echo experiment. Here, with B_1 gradients, the experiment is especially simple and robust. It is sketched in Figure 3 and starts with a B_1 gradient pulse $(g_1)_x$ along the x direction of the rotating frame of duration δ , separated by a 'diffusion interval' Δ from a second gradient pulse of duration identical to the first one (δ), immediately followed by a read pulse which probes the longitudinal magnetization (the read pulse may be

Table 1 Properties of B_1 vs. B_0 gradients

	B_1 gradients	B_0 gradients
Rise and fall times	$< 1 \mu\text{s}$	$\geq 100 \mu\text{s}$
Eddy currents	None	Important, can be greatly attenuated by self-shield
Perturbation of the static magnetic field and lock system	None	Strong
Effects of magnetic susceptibility variations across the sample	None	Important, must be compensated for
Effects of short T_2	Reduced by a factor of two	Full
Maximum strength (1997)	800 mT m^{-1}	10 T m^{-1}
Spatial directions available	1–2	3
RF deposition	High (improper for medical applications)	Low (limited to short RF pulses)

Figure 3 The simplest experiment for measuring self-diffusion coefficients by RF gradient pulses (shaded rectangles). $+x$ and $-x$ denote the RF phases. The simple phase cycling ($\pm x$), corresponding to two successive experiments whose results are coherently added, eliminates any transverse component of magnetization. The $(\pi/2)$ pulse is a standard read pulse.

incorporated into the second gradient pulse). This experiment can be understood as follows. The first gradient pulse is assumed to totally defocus nuclear magnetization, while the second one would act in a refocusing fashion provided that no motion occurred during Δ . Because of translational diffusion, the refocusing effect is not complete and some attenuation is observed at a rate depending on the self-diffusion coefficient D . The simple phase alternation $(g_1)_{\pm x}$ of the second gradient pulse eliminates any transverse magnetization contribution so that what is left is longitudinal magnetization whose amplitude decays according to (provided that $\Delta \gg \delta$):

$$\exp(-\Delta/T_1)\exp(-\gamma^2 g_1^2 \Delta \delta^2 D) \quad [4]$$

where T_1 is the longitudinal relaxation time and g_1 the gradient strength. In practice, this decay is monitored by the last $\pi/2$ pulse (which converts the longitudinal magnetization into observable transverse magnetization) as a function of δ^2 and a semilogarithmic plot (for instance) provides D . An important point is that the additional attenuation due to relaxation involves T_1 and not T_2 as in the PFGSE experiment (in many systems of interest T_1 has a relatively high value while T_2 may become very small). In these latter cases, when employing B_0 gradients, stimulated echo experiments (more complicated and more instrumentally demanding) must be available to avoid an unacceptable attenuation by relaxation phenomena. Another point in favour of B_1 gradients is the variation of magnetic susceptibility inside heterogeneous samples which is responsible for internal B_0 gradients at interfaces. This feature obviously affects B_0 gradient experiments and requires the application of compensatory external B_0 gradient pulses. Such complications are by nature absent in B_1 gradient experiments.

NMR Imaging by Radiofrequency Field Gradients

An early application of B_1 gradients in conjunction with spatial discrimination (imaging) is the so-called chemical shift imaging method; it is a two-dimensional experiment which produces chemical shift information in one dimension and spatial information (in the form of spin density) along the second dimension. This amounts to a one-dimensional experiment as far as spatial information is concerned. The experimental arrangement as well as the pulse sequence are very simple. It consists of using a surface coil (widely employed in biomedical applications of NMR), located upon the object under investigation and which therefore produces an inhomogeneous RF field along its axis. Applying an RF pulse of incrementable duration t_1 (this implies a series of experiments for each value of t_1) and acquiring the NMR signal immediately afterwards (according to the time variable t_2) generates a

signal $S(t_1, t_2)$ modulated in t_1 according to the spin density distribution and in t_2 according to the chemical shifts of the different species existing within the object. Because these modulations are in the form of sine or cosine functions, a double Fourier transform with respect to t_1 and t_2 yields the result indicated above. However, because the B_1 gradient (originating from the inhomogeneity of the surface coil) is far from being uniform and because the receptivity of this coil (which serves as well for detection purposes) is by nature strongly nonuniform, the results along the spatial dimension are obviously not quantitative. Nevertheless, the method has been widely used and is found very useful for obtaining the distribution of, for example, phosphorus metabolites. There are two instrumental prerequisites for obtaining quantitative spatial information: (i) a detecting coil with homogeneous receptivity and (ii) a coil delivering a uniform B_1 gradient. Clearly this corresponds to the arrangement of **Figure 2**. In practice, for making the experiment viable, the acquisition of spatial information must also be accomplished in a very short time (in a fraction of a second), as this is done by the read gradient in classical NMR imaging with B_0 gradients. These ideas led to the development of an experimental procedure adapted to B_1 gradients, which mimic the spatial encoding by a B_0 read gradient. The problem here is that acquisition of the NMR signal cannot take place while an RF field is on. The solution is indeed very simple and consists of applying the B_1 gradient in the form of short pulses separated by short intervals devoted to acquisition of the NMR signal. In practice a B_1 gradient pulse is followed by the acquisition of a single data point and the process is repeated until the NMR signal vanishes due to relaxation phenomena. The experiment is sketched in **Figure 4** and can be analysed as follows. Omitting relaxation effects and defining, for the l th data point, the time τ as lt , where τ is the duration of each individual gradient pulse, we can write the amplitude of the NMR signal (which appears in the form of a 'pseudo-free induction decay', pseudo-FID) as

$$S(k) = \int_{\text{object}} \rho(X) \sin(2\pi kX) dX \quad [5]$$

where $\rho(X)$ is the spin density at abscissa X (the gradient is assumed to act along the X spatial direction) and where the variable k , according to usual practice, is substituted to the variable t

$$k = (2\pi)^{-1} \gamma g_1 t \quad [6]$$

(g_1 is the gradient amplitude). It appears that there exists a Fourier relationship between S and ρ which can therefore be deduced from the following integral (inverse Fourier transform)

$$\rho(X) = \int S(k) \sin(2\pi kX) dk \quad [7]$$

yielding the object profile along X .

Figure 4 (a) Left: Different elementary slices subjected to the decreasing RF field produced by the gradient coil. Right: corresponding nutations assuming that nuclear magnetization was initially at thermal equilibrium. (b) Left: The RF gradient pulse train with interleaved detection windows leading to the acquisition of a pseudo-FID. Right: the Fourier transform of this pseudo-FID yields a profile representative of the object shape (see a).

A two-dimensional (X, Y) image, possibly after a slice-selection procedure along the Z direction, can be reconstructed from a series of profiles obtained at different orientations resulting from the sample rotation around Z . Moreover, every type of contrast used in MRI can also be considered with RF gradients. These contrasts can originate from relaxation times, diffusion coefficients and, most importantly, chemical shifts. This latter possibility is illustrated by **Figure 5** which shows separate images of two components in a solvent mixture, sorted according to their chemical shift.

RF Gradients in Pure High-Resolution NMR Spectroscopy

It is now well established that the judicious use of B_0 gradient pulses in a complicated multipulse (and possibly multidimensional) NMR experiment can lead to invaluable improvements in the quality of spectra, eventually lifting barriers which were thought to be impossible to overcome. This is especially true for the suppression of huge peaks such as those of solvent or of protons bound to a majority isotope (e.g. ^{12}C vs. ^{13}C in natural abundance). Another attractive feature concerns the suppression of phase-cycling procedures which can be replaced by appropriate gradient pulses in a single experiment, thus considerably reducing measuring times. Basically, the benefit of using gradients in high-resolution NMR relies on the possibility of defocusing all magnetizations and, by the end of the experiment, selectively refocusing the

Figure 5 (a) Full image of a polymer rod that has been immersed in a solvent mixture (isooctane, ethanol, toluene). (b,c) Chemical shift selected images of isooctane and toluene, respectively, showing the different degrees of penetration.

desired magnetization(s) or coherence(s). (Throughout, gradient strengths and gradient pulse durations are supposed to entail a complete defocusing, i.e. a complete disappearance of the NMR signal.) Actually refocusing can be achieved in two ways: (i) by applying a gradient pulse of the same strength and same duration with an inverse polarity, thus producing the same precession in the reverse direction and (ii) by applying exactly the same gradient pulse after a 180° RF pulse which changes the sign of magnetization and amounts to reversing the gradient sign. Now, if the 180° pulse is selective, the only magnetization which survives (i.e. which has been refocused) is the one corresponding to the bandwidth of the 180° selective pulse. These simple considerations show how it is possible to manipulate gradients in order to preserve one resonance while destroying all the others. In fact, gradients can accommodate much more complicated schemes involving coherences of different orders and selection of a given coherence pathway. It can be recalled that coherence orders stem from the state of the spin system in the course of the experiment. For instance, in the case of two weakly coupled nuclei of spin- $\frac{1}{2}$, denoted A and X , the coherence orders are as follows (I_+ and I_- are the classical raising and lowering operators): $p=0$, longitudinal magnetization or zero quantum coherence (represented by e.g. $I_+^A I_-^X$); $p=\pm 1$, single quantum coherences corresponding to observable transverse magnetization; $p=\pm 2$, double quantum coherences (represented by e.g. $I_+^A I_+^X$).

Recognizing that a coherence of order 0 is not affected by B_0 gradients, that defocusing of a double quantum coherence is twofold, the defocusing of a one-quantum coherence and that the sense of defocusing is given by the sign of the coherence order, it can easily be recognized that the coherence pathways leading to a final observable signal must satisfy the simple equation

$$\sum_i p_i g_i = 0 \quad [8]$$

where p_i and g_i are respectively the coherence order and the gradient strength relevant to the i th interval of the considered experiment. This equation is in fact valid for homonuclear experiments; in a heteronuclear experiment, gyromagnetic ratios must be introduced as multiplying factors. At this point, it must be emphasized that the above discussion applies to B_0 gradients, i.e. to precession (or rotation) in the transverse (x, y) plane. If one assumes that these B_0 gradients are sufficiently strong so that the natural precession (due to chemical shift) is negligible, a full equivalence with B_1 gradients can be established by recognizing that the latter correspond to the same type of rotation in the vertical plane of the rotating frame. Consequently, this equivalence amounts

to flipping the vertical plane into the xy plane and, after the B_1 gradient application, flipping it back to its initial position. This is achieved by clusters of the type

$$\begin{aligned} &(\pi/2)_x(g_1)_y(\pi/2)_{-x}; (\pi/2)_{-x}(g_1)_{-y}(\pi/2)_x; \\ &(\pi/2)_{-y}(g_1)_x(\pi/2)_y; (\pi/2)_y(g_1)_{-x}(\pi/2)_{-y} \end{aligned} \quad [9]$$

where $(\pi/2)$ stands for a standard hard pulse (homogeneous) and (g_1) for the application of an RF gradient of sufficient strength and duration (to produce a complete defocusing); RF phases are indicated as subscripts. By means of this equivalence, the numerous experiments involving B_0 gradients can easily be transposed with B_1 gradients and will not be discussed further.

The emphasis will rather be put on two simple and illustrative experiments which take advantage of the specific features afforded by RF gradients. In principle they could be converted into B_0 gradient experiments by using the reciprocal of eqn [9]; however, due to the inherent shortcomings of B_0 gradients (especially rise and fall times) and to the complexity of the resulting sequences, this is not practicable. The first example deals with solvent peak suppression. Among several possibilities allowed by B_1 gradients, the one using a train of

Figure 6 Suppression profile resulting from the sequence shown at the top of the figure and obtained by repeating the experiment for a series of transmitter frequencies. When the signal is on-resonance, it is selectively defocused by the train of RF gradient pulses (g_1). τ is chosen so that the first sideband (2π precession) is outside the spectrum of interest.

short gradient pulses appears somewhat specific and difficult to convert into a B_0 gradient version. It works in the manner of a DANTE (delays alternating with nutations for tailored excitation) sequence. It can be recalled that the train of short, homogeneous RF pulses (each corresponding to a small flip angle) of a DANTE sequence is equivalent to a selective pulse because the effect of pulses is cumulative only for on-resonance magnetization. Magnetizations corresponding to other resonance frequencies are tipped back to the z axis (to their equilibrium position) in the course of the pulse train. If, instead of homogeneous pulses, RF gradient pulses are used, selectivity is of course retained, but their effect is to defocus that magnetization which is on-resonance and thus to suppress the relevant signal. The efficiency of this procedure is illustrated in **Figure 6** where a sufficient number of cycles (n) effectively lead to complete on-resonance peak suppression.

Another appealing feature of RF gradient pulses is their ability to select coherences, and this will be discussed here for systems of spin- $\frac{1}{2}$ nuclei. A p-spin high-pass filter is indeed achieved by the following cluster of two B_1 gradient pulses of respective phases x and y :

$$(g_1)_x (rg_1)_y; \quad r = p/(p-1) \quad [10]$$

rg_1 denoting a second gradient pulse that is r times longer than the first one. r is actually set according to the desired order of filtering, meaning that one-spin systems are rejected for $r=2$, one- and two-spin systems are rejected for

$r=3/2$ (**Figure 7**) and so on. Before going into detail for a particular spin system, it can be anticipated that the filtering properties should rest on antiphase coherences rather than on multiple quantum coherences as might be the case with B_0 gradients. To make this statement clearer, it can be recalled that an antiphase A doublet (one line positive, the other negative) of a two-spin AX system is represented by the operator product $2I_x^A I_z^X$ (provided the two A lines are along the x axis of the rotating frame). Now, B_1 gradients acting in vertical planes (e.g. x,z or y,z) are prone to operate on such antiphase coherences rather than on multiple quantum coherences (e.g. of the type $2I_x^A I_y^X$). In order to clarify this point, consider the A coherences which can exist after an evolution interval following a standard $\pi/2$ pulse: I_x^A , I_y^A , $2I_x^A I_z^X$, $2I_y^A I_z^X$ and let θ be the angle of nutation produced by g_1 for a given spatial location, acknowledging that, at the outcome, an average over all possible values of θ must be performed (for sufficient gradient strength and duration: $\langle \sin \theta \rangle = \langle \cos \theta \rangle = 0$, $\langle \sin^2 \theta \rangle = \langle \cos^2 \theta \rangle = 1/2$). From these considerations, it is easy to derive the way in which the various coherences transform under the gradient cluster $(g_1)_x (2g_1)_y$:

$$\begin{aligned} I_r^A &\xrightarrow{(g_1)_x (2g_1)_y} 0 \\ I_y^A &\xrightarrow{\quad} 0 \\ 2I_x^A I_z^X &\xrightarrow{\quad} 0 \\ 2I_y^A I_z^X &\xrightarrow{\quad} (2I_y^A I_z^X) / 1 + (2I_x^A I_z^X) / 4 \end{aligned}$$

Figure 7 Reference (top) and 3 spin-filtered (bottom) spectra. The latter has been obtained with the sequence shown at the top of the figure ($r=3/2$; see text). The time τ is chosen so that antiphase coherences can develop; the last $\pi/2$ pulse is for purging purposes.

Clearly, all quantities cancel (including those corresponding to a single spin system) except the antiphase coherence $2I_y^A I_z^X$, scaled down by a factor 4 and which leads to the corresponding quantity transferred to the X nucleus. Thus, in addition to its filtering properties, this gradient cluster affords transfer capabilities suitable for two-dimensional correlation spectroscopy without the need of phase cycling procedures.

R	distance between two incoherent point sources
R_L	lateral spatial resolution
λ	wavelength of light
$\phi_{\max}$	half-angle of the maximum cone of light collected by the lens

Introduction

Vibrational Raman and infrared microspectroscopy are analytical tools that characterize both the chemistry and the physical structure of materials. These methods combine two separate approaches, vibrational spectroscopy and light microscopy, for elucidating chemical systems at the micron and the submicron levels. Whereas vibrational spectroscopy probes the details of molecular composition, light microscopy reveals sample morphology based on the variations in optical properties. Vibrational microscopy builds on both of these techniques, and thus provides chemically selective visualizations of microscopic samples. Domains within complex samples, ranging from diamond inclusions in a mineral to malignant cells in a tissue biopsy, may be examined with Raman and infrared techniques. The efficacy and flexibility of vibrational microspectroscopy is highlighted by its wide adoption in diverse areas such as geology, medicine, forensic science, and industrial process control.

Since the theoretical background and practical implementation of vibrational spectroscopy are described elsewhere in this encyclopedia, the emphasis here will be on the extension of Raman and infrared spectroscopy to the microscopic realm. It should be noted that many of the methods described here are applicable to other microspectroscopic methods, especially those based on optical phenomena such as fluorescence.

The balance between spectroscopy and microscopy distinguishes one vibrational microscopic technique from

another. At one extreme, spectroscopic and microscopic analyses are carried out separately. In a typical arrangement, the sample is examined through a microscope under white-light illumination, and then either Raman or infrared spectra are recorded at one or more selected points. Approaches that more fully integrate the acquisition of morphological and spectroscopic data have also been developed. Mapping techniques record spectra at successive points or lines within the sample; the spectra are combined to provide a view of the sample at specific vibrational frequencies. Imaging techniques, by contrast, record spectra simultaneously for contiguous points within a given sample area.

Mapping and imaging methods allow for sample visualizations over sequential wavelength intervals. The data sets are represented by a three-dimensional 'image cube' having two spatial and one spectral dimension (see **Figure 1**). Depending on the orientation, two-dimensional slices along

Figure 1 Mapping and imaging data can be depicted as an 'image cube' having two spatial and one spectral dimension.

a particular axis yield either a set of image planes stacked as a function of wavelength or a group of spatially resolved spectra. Vibrational spectroscopic mapping and imaging combine the morphological and chemical analyses of microscopic systems and reveal trends that are often difficult to extract from bulk or isolated single-point measurements.

Instrumentation

A standard Raman or infrared microspectrometer consists of an excitation source, a compound microscope, a spectrometer, and a detector. As in bulk techniques, the design of microspectroscopic experiments is guided by the sample composition as well as demands for frequency response, sensitivity, data acquisition rates and spectral resolution. Factors specific to vibrational microspectroscopy include the spatial resolution and the optical throughput between the microscope and the spectrometer.

Sources

Raman microspectroscopy is usually implemented from the ultraviolet to near-infrared wavelength regions, from approximately 0.3 to 1.5 μm . Excitation with sources such as Ar^+ , HeNe and solid-state lasers is standard. Infrared microspectroscopy, by contrast, is usually carried out between 0.78 and 25 μm with broadband sources such as quartz lamps or ceramic globars. More recently, excitation with synchrotron radiation has also been demonstrated for infrared measurements.

The Compound Microscope

The compound microscope is central to vibrational microspectroscopy. The optical components and light paths for both refractive and reflective microscopes are shown in **Figure 2**. As illustrated, a compound microscope contains a light source, a condenser, an objective, various apertures and an ocular. The sample is first visualized under white light to aid in observation and alignment. The condenser illuminates the sample, and the transmitted light is collected by the objective. Light also can be reflected (or scattered) from the sample; in this configuration, which is known as epi-illumination, the objective also serves as the condenser. In either case, an inverted and usually enlarged image of the sample is formed at the back focal plane of the objective. This intermediate image is relayed either through collection optics to a video camera or through the ocular, which further magnifies the image for viewing. Microscopes tailored for operation at ultraviolet and infrared wavelengths usually contain a parfocal white-light path for sample observation.

Figure 2 Schematics of (a) refractive and (b) reflective microscopes.

Following the preliminary microscopic examination, the spectroscopic source is introduced on to the sample. In Raman microspectroscopy, the probed region is defined by the size of the impinging laser beam. For infrared applications, the radiation is localized within a given area in part by placing an aperture between the source and the sample. An image of the irradiated area, corresponding to the Raman or infrared signal, is formed behind the objective, and is diverted to the spectrometer for analysis. The optical path of the vibrational signal is configured such that it focuses in the same plane as the white-light image; the parfocal light paths ensure that identical sample regions are examined in both procedures, while maximizing the optical throughput.

Microscope Lenses

Microscope lenses are complex assemblies that are designed to balance the requirements for magnification, focal length and light collection with various factors that degrade image fidelity (note that the optics in **Figure 2** are simplified for clarity). Refractive and reflective optics exhibit aberrations that cause image blurring and deformation. These include effects such as spherical aberrations and astigmatism. Refractive optics also exhibit chromatic aberrations which cause light of different wavelengths to focus at separate points.

The highest-quality images are generally obtained with light microscopes that contain refractive glass elements. Visible Raman microspectroscopy, in particular, benefits from the mature optical technology that has been developed for visible wavelengths. Refractive optics are

Figure 3 The numerical aperture is defined as $n \sin \phi$, where n is the refractive index of the surrounding medium and ϕ is the half-angle of the cone of light collected by the optic.

available for vibrational microspectroscopic applications at other wavelengths; examples include quartz for the ultraviolet and germanium for the infrared. Reflective optics can also be tailored for different wavelength intervals and typically consist of glass substrates coated with a metallic layer. Since they do not exhibit chromatic aberration, reflective optics are particularly useful when large wavelength intervals are covered, as in mid-infrared microspectroscopy.

A standard optic in a reflective microscope is the Schwarzschild (also referred to as Cassegrainian) lens; it can be used as both a condenser and an objective. As depicted in **Figure 2b**, the Schwarzschild lens is centrally obscured, which reduces the amount of light collected compared with a refractive optic of similar dimensions. Since the optic is reflective, chromatic aberration is not a concern, but the spherical design can lead to image warping.

It is standard to label objectives with the numerical aperture, NA , which is a measure of the light-gathering capability of an optic:

$$NA = n \sin \phi_{\max} \quad [1]$$

where n is the refractive index of the medium between the sample and objective and $\phi_{\max}$ is the half-angle of the maximum cone of light collected by the lens (see **Figure 3**). In a given apparatus, the NA of the objective, relay optics and spectrometer aperture are matched for optimum light collection.

Vibrational objectives typically operate in air, which has a refractive index near unity; the highest NA value obtained in air is approximately 0.95 using refractive visible objectives. By changing the surrounding medium, and thus n , it is possible to obtain values greater than 0.95. Immersion objectives operating under media such as water or oil achieve NA values greater than 1. For mid-infrared applications, the maximum NA for reflective objectives is approximately 0.65. For optimal image formation, it is important to follow the manufacturer's specifications for thickness and refractive index of slides and coverslips (if applicable).

Spatial Resolution

Diffraction effects influence the spatial resolution of a vibrational microspectroscopic measurement. To illustrate consider, for example, monochromatic light from a point source as it propagates through the objective. The image that forms at the focal plane of the objective is not a point, but rather a diffraction pattern consisting of alternating light and dark concentric circles. The bright central disc in the pattern is known as the Airy disc, with a radius r_A given by

$$r_A \approx 0.61 \lambda / NA_{\text{obj}} \quad [2]$$

where λ is the wavelength of light and NA is the numerical aperture of the optic.

Two incoherent point sources of equal brightness lying in a plane perpendicular to the objective are just resolved when

$$R \approx 1.22 \lambda / (NA_{\text{obj}} + NA_{\text{cond}}) \quad [3]$$

where R is the distance between the two points and NA_{obj} and NA_{cond} are the numerical apertures of the objective and condenser, respectively. Equation [3] is known as the Rayleigh criterion, and is a standard measure of the lateral spatial resolution. For an epi-illumination measurement, eqn [3] is recast as

$$R \approx 0.61 \lambda / NA_{\text{obj}} \quad [4]$$

From eqns [3] and [4], it is seen that the optimum spatial resolution is obtained when objectives with high NA are used for measurements at short wavelengths.

The spatial resolution criteria given in eqns [3] and [4] apply for diffraction-limited microscope objectives in the far-field limit. In recent years, near-field techniques have been devised that exceed the diffraction limit by scanning a tapered light source, with a spot size less than the probe wavelength, in close proximity to the sample.

Spectrometers

Dispersive elements and interferometers are widely used in vibrational microspectroscopy. As in bulk measurements, microscopic Raman studies are carried out with grating monochromators, spectrographs or Fourier transform spectrometers. Infrared microspectroscopy, by contrast, is almost exclusively a Fourier transform technique.

At visible and near-infrared wavelengths, vibrational microspectroscopy is also implemented with solid-state filters, particularly in imaging applications. Electronically driven devices such as acousto-optic and liquid crystal filters provide the tunability and moderately narrow passbands required for spectroscopic imaging. These high-speed filters contain no moving parts and can be

custom-built to provide spectral resolutions of less than 10 cm^{-1} over large spectral ranges. Acousto-optic tunable filters (AOTFs) consist of a piezoelectric transducer bonded to a birefringent crystal such as TeO_2 . When an RF frequency is applied to the crystal, an acoustic wave is generated that diffracts light over a narrow spectral interval. The AOTF passband is modified by varying the input RF frequency.

Another useful solid-state device is an interference filter fabricated from a set of liquid crystals. The birefringent properties of a liquid crystal tunable filter (LCTF) can be varied by applying an external voltage across a crystal axis. A filter is constructed from a series of polarizers and liquid crystals. A particular passband is selected by tuning the individual liquid crystal elements.

Thin-layer interference filters with passbands between 18 and 50 cm^{-1} are also applied in microspectroscopic imaging. These devices can be tuned over large wave-number ranges by varying the angle of incidence. Broader wavelength coverage may be obtained with a series of filters, which can be placed in a device such as a filter wheel.

Detectors

The detectors used in vibrational microspectroscopy operate by transducing either the capture of a photon or a minute change in temperature into an electrical response. Both photon and thermal detectors are used individually or configured into an array. The single-point detectors that comprise the array detector are known as picture elements or pixels. **Table 1** lists the wavelength ranges and operating temperatures of several array detectors that are used in Raman and infrared microspectroscopy and imaging.

For the visible to near-infrared region, charge-coupled device (CCD) detectors have been widely adopted for single-point, mapping and imaging Raman microspectroscopy. These photosensitive arrays, in most cases, are monolithic silicon devices that can be fabricated with millions of individual pixels. The wavelength response of CCDs generally declines in the red, cutting off at about $1.1\text{ }\mu\text{m}$ the band-gap of silicon. For this reason, CCDs have limited application in near-infrared microspectroscopy.

For infrared microspectroscopy, single-element detectors are used for point and mapping measurements. More recently, array detectors have been applied for spectroscopic imaging. In infrared focal plane arrays, the

monolithic silicon design used in CCDs is replaced by a hybrid construction. In a hybrid detector, photon detection occurs in a semiconductor layer (indium antimonide, mercury cadmium telluride and doped silicon are typical detector materials), while the readout and amplification stages are carried out in a silicon layer. The two layers are electrically connected at each pixel through indium 'bump-bonds'. Other innovations such as microbolometer arrays also show promise for spectroscopic imaging applications.

Raman Microspectroscopy

Point Microscopy

Raman microspectroscopy is routinely implemented using epi-illumination. As shown in **Figures 4**, the objective directs the laser excitation onto the sample and collects the light scattered from the surface. Often fibre optics are used for safe and convenient optical coupling of the microscope to the laser and spectrometer. In point microspectroscopy (**Figure 4**), the Raman signal from a small spot on the sample is dispersed by a grating spectrometer and focused onto a CCD detector. The constituent wavelengths are measured by one or more pixels along a long narrow strip on the CCD. The undesired Rayleigh scattered light, corresponding to the laser excitation wavelength, is removed by placing one or more holographic or dielectric notch rejection filters between the microscope and the spectrometer. Various grating designs, such as dual-stage and subtractive monochromators, also may be used to remove the laser excitation, but are less optically efficient than instruments that incorporate notch rejection filters and single-stage monochromators.

Confocal Raman Microscopy

Optical sectioning of a sample may be achieved with confocal Raman microscopy. This technique rejects out-of-focus light by introducing pinhole apertures into the optical train of the microscope. A confocal scheme is shown in **Figure 5**, where one aperture is placed between the laser and the objective, and another is placed at the image plane of the objective. The apertures block the light scattered from regions outside the focal plane of the objective. Crisp images of thin optical sections may be obtained by mapping the sample point by point. Furthermore, a three-dimensional

Table 1 Properties of various array detectors

Figure 4 Several different approaches employed in vibrational microspectroscopy. (a) Point measurements: vibrational spectra are obtained at individual, selected points within the sample. (b) Point mapping: spectra are recorded at successive spots within the sample. (c) Mapping is also carried out with line excitation. (d) Spatial encoding methods such as Hadamard transform imaging: a physical mask blocks part of the signal from reaching the detector. A series of images is obtained with the mask in different positions, and then the data are converted to wavelength-dependent images through a Hadamard transform. (e) Direct imaging: the spectroscopic image is obtained by recording the signal from all points on the sample simultaneously over a narrow spectral interval. A series of images at discrete wavelengths is recorded to provide spectroscopic information for each pixel.

Figure 5 Confocal microscopy: pinhole apertures placed in the optical train of the microspectrometer lead to rejection of out-of-focus light.

image of the sample may be constructed by carrying out measurements at different sample depths.

Mapping

Mapping techniques scan the excitation source or the sample in a raster or line pattern (see **Figures 4b** and **4c**). In a raster scan, spectra may be recorded at successive points by moving either the sample or source on a motorized platform. Mapping may also be implemented by irradiating the specimen with a line source. In one method, a line is produced by rapidly sweeping the laser beam back and forth with a mirror powered by a piezoelectric transducer. It is also possible to focus the laser beam into a line with cylindrical optics. High-precision designs for mapping apparatus minimize mechanical instabilities and positioning errors.

For point mapping, the Raman signal is recorded as in single-point measurements. When the excitation is along a line, the Raman signal is collected through the objective, directed onto a grating and dispersed on to a CCD. The two-dimensional detector then records the spatial information along one axis and wavelength data along the other. An image cube is gradually built up as the line is moved across the full sample area.

Imaging

As shown in **Figures 4d** and **4e**, point and line excitation are replaced by wide-field irradiation in both spatial encoding and direct imaging methods. In a common arrangement, a given sample area is illuminated by defocusing the laser through a beam expander prior to the objective. The sample illumination is not perfectly uniform in this configuration because the intensity distribution of the laser beam (typically Gaussian) is preserved. Other properties of monochromatic coherent excitation may also affect the image quality. Despite the experimental concerns, wide-field illumination is useful

when dealing with fragile specimens, since the power density is reduced, thus minimizing damage from thermal or photolytic processes.

Hadamard Transform Imaging

Spatial encoding methods such as Hadamard transform imaging also can be used for the spectroscopic visualization of samples. More recently, developments in digital microarray technology will likely provide a convenient new approach for spatial encoding from the mid-infrared to the ultraviolet. In one common arrangement, the entire sample area is irradiated with wide-field, epi-illumination (**Figure 4d**). Part of the Raman signal emanating from the sample is blocked with a mask containing a series of apertures. The spatially filtered signal is focused on to an entrance slit of a monochromator, which disperses the signal across a two-dimensional array detector. The slit preserves one image axis while the Hadamard mask is used to encode the other axis. Subsequent measurements are carried out with the mask in different positions. Each measurement corresponds to the Raman signal from the unmasked points on the sample along one spatial axis over the entire spectral range of interest. The experiment is designed such that the number of independent measurements equals the number of points on the sample. The spatially dependent images are then converted to spectroscopic images through a Hadamard transform. Unlike the other methods mentioned in this article, Hadamard spectroscopic imaging systems are limited to research activities and are not yet commercially available.

Direct Imaging

Raman microscopic imaging can also be carried out by imaging the sample through an interferometer or filter (shown in **Figure 4e**). The sample is irradiated with wide-field, epi-illumination and then modulated or filtered images are recorded with a CCD. Spectroscopic information is obtained by recording sequential images over a range of optical retardations in the case of the

Figure 6 A Raman spectroscopic image of 1 μm diameter polystyrene beads. The spectroscopic image on the left exhibits bright regions that correspond to the Raman signal at 1000 cm^{-1} shift, a symmetric aromatic ring vibration. A series of images was recorded between 747 and 1363 cm^{-1} shift; a spectrum is then available for every spatial resolution element in the image. The trace on the right corresponds to the spectrum of a single pixel from the centre of a single polystyrene bead.

interferometer or a range of frequencies in the case of the tunable filter. In this way, spectra corresponding to various points within the sample are obtained at each detector pixel. Since the image is captured in its entirety, the results are not prone to mechanical positioning errors that may occur in point or line mapping methods. The image quality, in fact, is primarily limited by diffraction. When image shifts occur in direct imaging, they are usually predictable and can be compensated by either experimental or computer procedures.

The basic principles of Raman microscopy and imaging are encapsulated by **Figure 6**, which depicts a Raman image and a spectrum of a $1\text{ }\mu\text{m}$ diameter polystyrene bead. The data were obtained with a microscope coupled to a CCD array; individual images were recorded through an AOTF, which was successively tuned between 747 and 1363 cm^{-1} from the exciting 647 nm Kr^+ laser line. The Raman image shown was recorded at 1000 cm^{-1} , corresponding to a symmetric aromatic ring vibration in polystyrene. The bright areas correspond to areas rich in polystyrene, thus revealing the distribution of beads in the sample. A spectrum for every pixel is available because images were recorded over a series of wavelengths. **Figure 6** illustrates a spectrum obtained from a single pixel in one of the bead centres.

Infrared Microspectroscopy

Infrared microspectroscopy is based on either transmission or reflection measurements. Transmission is the simplest implementation; the maximum sample thickness

is sample and wavelength dependent, however, and is limited to approximately $15\text{--}20\text{ }\mu\text{m}$ for mid-infrared measurements. Reflection measurements are indispensable for samples that are thick or opaque. Various microscope objectives have been tailored for measurements based on the corresponding bulk infrared techniques, such as diffuse reflectance attenuated total reflectance and grazing angle reflectance.

Optical effects such as stray light or scattering are treated by placing one or more apertures in the optical train of the infrared microscope. For transmission measurements, one aperture is placed between the condenser and the sample and another is placed between the objective and the image plane. The two apertures are matched in size in order to optimize the signal. For reflectance measurements, only one aperture is used. This type of arrangement is widely employed in infrared spectroscopy, and is known as 'redundant aperturing'.

Single-Point Measurements

Most single-point infrared microspectroscopy is implemented with Fourier transform spectrometers, for which the well-known multiplex and throughput advantages generally apply. The multiplex advantage arises because all of the input radiation is detected over the entire scan time; however, it applies only when the dominant source of noise is the detector. When the detection is shot-noise limited, as with CCDs, the multiplex advantage does not hold. The throughput advantage for interferometers arises from the use of circular apertures. Dispersive instruments, by contrast, require narrow exit and entrance

Figure 7 Infrared microspectra of cotton fibres collected in a forensic application. The spectrum of a fibre retrieved from a bullet (top trace) is seen to match the spectrum of a fibre from the police officer's vest (bottom trace). Data courtesy of John A. Reffner, Spectra-Tech, Inc. and Ronald P. Kaufman, Maine State Police Crime Laboratory.

slits, particularly for higher spectral resolution. Furthermore, a circular aperture provides a more convenient geometry for coupling a microscope to the spectrometer.

Trace amounts of sample can be analysed with infrared microspectroscopy. The technique, for example, is a standard tool in forensic science. **Figure 7** illustrates fibre spectra that were key evidence in a criminal investigation. A cotton fibre fragment, which was recovered from the nose of a bullet, was matched spectroscopically to fibres from the vest of a police officer who had been shot. Fibre samples represent a system that is difficult to examine with bulk techniques, but which is amenable to vibrational microscopic analysis.

Mapping and Imaging

Infrared mapping and imaging approaches are applied as in the corresponding Raman approaches, with the appropriate choices for source, spectrometer, and detector. For example, a combination of an acousto-optic filter and an InSb focal plane array can be used to record frequency-dependent images in the near-infrared. In the mid-infrared, direct images are recorded with a step-scan interferometer coupled to an infrared focal plane array detector. To illustrate, consider a transmission measurement in which a step-scan interferometer modulates the output from a blackbody source. The infrared radiation is directed on to the sample with the condenser. The transmitted infrared radiation is collected by the objective and then focused on to the array detector. Over the course of the scan, the movable mirror in the interferometer is paused for several milliseconds at every step in order to

record the image. At the completion of a single scan, a complete interferogram is generated at each detector pixel. The interferograms are then converted to frequency by standard Fourier transform processing.

As an example of the Fourier transform infrared imaging technique, **Figure 8** depicts an infrared spectroscopic image of human breast cells which was recorded with a 64×64 mercury–cadmium–telluride (MCT) array. The data set then encompasses 4096 separate interferograms, one for each pixel. Spectra are obtained through standard Fourier transform procedures. The resulting data cube contains the set of image planes stacked as a function of frequency. Each image exhibits contrast based on the differences in infrared spectral response, which in turn reflects the variation in the chemical composition within the sample. **Figure 8** depicts one such image plane at 2927 cm^{-1} , which corresponds to a protein and lipid infrared molecular marker (CH_2 antisymmetric stretch). In this way, the distribution of biochemical species can be visualized across the sample. More detailed chemical information can be obtained by examining the infrared spectra that are associated with each pixel in the image.

Sampling Considerations in Image Generation

The Nyquist theorem specifies that a sinusoidal function in time or distance can be regenerated with no loss of information as long as it is sampled at a frequency greater than or equal to twice per cycle. The Nyquist theorem must be considered in direct imaging applications because

Figure 8 An infrared spectroscopic image of human breast cells. The spectroscopic image on the left exhibits contrast based on the intensity of the absorption band centred at 2927 cm^{-1} (antisymmetric CH_2 stretch), which contains contributions from both the lipid and protein fractions within the cell. Since images are obtained over a contiguous wave number interval, it is possible to construct a spectrum for every image pixel. The spectrum extracted from one of the cells is shown on the right.

the signal is sampled by the discrete pixel elements in an array. Consider a diffraction-limited arrangement with a lateral spatial resolution R_L . If the total magnification M_{tot} is a product of the magnifications of the microscope objective M_{obj} and the projection lens M_{proj} , the Nyquist theorem requires

$$M_{\text{tot}} R_L \geq 2p \quad [5]$$

where p is the pixel size. That is, the sampling interval must be at least twice the highest spatial interval. If the smallest resolvable feature is $5\text{ }\mu\text{m}$, then each detector pixel must sample intervals that are $\leq 2.5\text{ }\mu\text{m}$. As long as eqn [5] is obeyed, the spatial fidelity of the microscopic image is preserved and sampling artifacts are avoided. It follows that oversampling does not provide any additional information; this is also known as empty magnification.

Introduction

Raman optical activity (ROA), which is most often measured as the circular intensity difference (CID, the difference between a Raman spectrum excited with right circularly polarized light and that excited with left circularly polarized light), is a very small effect which can be easily obscured by artifacts. It can also be reported as the dimensionless circular intensity difference (DCID, $[I^R - I^L]/[I^R + I^L]$). The first ROA spectrometers were normal scanning Raman spectrometers modified by adding devices to modulate the polarization of the exciting laser beam. Measurements done on this instrumentation were plagued by artifacts and took up to 40 h to record a spectrum. Therefore relatively few spectra were measured before the advent of a new generation of spectrometers. Two main technical advances characterize the construction of these sensitive instruments: firstly the development of multichannel detectors culminating in backthinned CCDs which are practically ideal light detectors (with quantum efficiencies of about 80% at the wavelength of peak sensitivity), and secondly the development of the holographically manufactured line filter. The first improvement shortened the time of measurement to about 20 min for pure samples and allowed the measurement of dilute samples in a few hours, and the second allowed the replacement of multiple monochromators by a single polychromator with much higher optical throughput. Later the use of a backscattering arrangement was added to further improve the spectra. As these newer spectra are of much higher quality, mainly the relatively recent literature is covered in this article. For historic data, the interested reader is directed to earlier reviews given in the Further reading section.

[☆]This article represents the situation in the mid-1990s. Considerable developments have taken place since then, and small molecule and macromolecule applications are now considered separately in articles on pages 2369 and 2378.

In a typical modern ROA instrument, a linearly polarized laser beam is directed through a Pockels cell, which renders the beam circularly polarized. With a frequency of a few hertz the exciting radiation is switched between right circularly and left circularly polarized and focused onto the sample. In the latest spectrometers the Raman effect is observed in the so-called 180° or backscattering arrangement. This method of observation is achieved by drilling a hole into a plane mirror through which the exciting laser beam may pass. The mirror then reflects the backscattered part of the excited radiation through a highly efficient holographically manufactured notch filter to remove the Rayleigh radiation. The Raman radiation, having passed through a Lyot depolarizer to prevent polarization artifacts, can then be processed by a polychromator that consists of a slit and a single grating to finally reach the detector, a backthinned CCD chip.

As in normal Raman spectroscopy, two methods of detection are possible when not using the backscattering arrangement: through a linear polarizer horizontal to the scattering plane (those spectra are called depolarized) or through a vertical polarizer (polarized spectra).

To be useful for structural determinations, ROA spectra have to be compared with calculated spectra. Models confined to special functional groups or semiempirical calculations have been used with limited success for this purpose but *ab initio* studies are now possible. These calculations, especially the time-consuming ones with large basis sets or even with the inclusion of configurational interaction, allow for useful derivation of absolute configuration or even conformation of the molecules under study when compared with experimental data.

Stereochemistry of Small Chiral Molecules

One of the simplest chiral molecules one can imagine is bromochlorofluoromethane [1]. As a liquid which until now has only been obtained as an enriched but not pure substance, no crystal structure suitable to deduce the absolute configuration could be obtained. It is therefore a great success for ROA, together with *ab initio* calculations, that it is possible to deduce the absolute configuration of this molecule by comparing experimental and calculated spectra. Figure 1 shows the depolarized Raman and ROA spectra of

Figure 1 Depolarized Raman (upper curve) and ROA (lower curve) spectra of (–)-CHFCIBr together with the calculated spectra (middle curves) for the (*R*)-isomer. Reproduced with permission of Wiley-VCH from Costante J, Hecht L, Polavarapu PL, Collet A, and Barron LD (1997) *Angewandte Chemie International Edition in English* 36: 885–887. CHFCIBr [1] (36 % enantiomeric excess) together with the calculated spectrum of the (*R*)-enantiomer. Seven of the nine ROA band calculations arrive at the correct sign.

The well-known molecule (2*R*,3*R*)-(+)-tartaric acid [2] has been studied both as its *d*₀ and *d*₄ isotopomers. As small molecules are less demanding concerning computation time, the molecule could be studied at three theoretical levels: *ab initio* calculations using the 6-31G, 6-31G* and DZP basis sets were performed and compared with the

experimental spectra. The molecule was found to exist as a single conformer in aqueous solution, i.e. the conformation with the carboxylic groups *trans* to each other.

A comparison between VCD (vibrational circular dichroism) and ROA spectra of the four structurally similar molecules *trans*-pinane [3], *cis*-pinane, α - and β -pinene together with theoretical calculations shows that the ratios of the respective parent technique (IR or Raman spectroscopy) to its chiral counterpart are by a factor of 3 in favour of ROA. This advantage is, unfortunately, cancelled by the somewhat more difficult method of measurement. Quantitative comparisons enlighten the supposition that VCD and ROA are highly complementary nonredundant stereochemical techniques.

The experimental and calculated (6-31G* basis set) spectra of (*R*)-(+)-dimethyloxirane [4] in the 200–1500 cm^{−1} region agree for the majority of bands. Depolarized, polarized and ‘magic angle’ Raman and ROA spectra have been measured. By setting the transmission axis of the analyser at the ‘magic angle’ of $\pm 35.26^\circ$ to the vertical, only contributions from the electric dipole–magnetic dipole polarizability are present in the ROA spectra. As expected, calculations at higher theoretical levels give better results for the calculation of normal modes, but for the calculation of the polarizability derivatives they do not show any remarkable advantage. This is very important for practical reasons, as one can use the less time-consuming calculations for the computation of ROA.

Methyl torsion Raman optical activity of *trans*-2,3-dimethyloxirane has been compared with that of *trans*-2,3-dimethylthiirane [5]. Torsion of the two methyl groups in these molecules can occur as in-phase and out-of-phase combinations. The former can be observed as a very weak and broad Raman band at ~ 200 cm^{−1} in the dimethyloxirane with positive ROA of medium size, whereas it is observed as a shoulder at ~ 220 cm^{−1} in the spectrum of the dimethylthiirane with large positive

ROA. Contrary to the dimethyloxirane spectra, the dimethylthiirane spectra also contain the out-of-phase torsion: it shows up as a medium size Raman band at $\sim 245\text{ cm}^{-1}$ with zero or small negative ROA. This is in good agreement with *ab initio* calculations and even with the old inertial model for methyl torsions.

From the Raman optical activity of *trans*-2,3-dimethylthiirane the absolute configuration has been determined. Its experimental spectrum is very similar to that calculated (*ab initio*, basis set 6-31G*) for the 2*R*,3*R*-isomer [5] with best agreement in the skeletal vibration region.

The vibrational spectrum of (*S*)-3-methylcyclopentanone [6] has been calculated on the 6-31G and on the 6-31G** level, whereas Raman optical activity has only been predicted on the 6-31G**/6-31G and on the 6-31G level. The calculations with the larger basis set did not show any improvements.

The ROA spectrum of (+)-3-methylcyclohexanone [7] shows some couplets, which gave rise to much discussion about their origin. Assignments of those vibrations were based on semiempirical calculations with limited reliability. The latest spectrum, however, together with an *ab initio* vibrational analysis, attributes, for example, the couplet at 494 and 518 cm^{-1} to a ring bending mode and an antisymmetric in-plane C=O bending motion coupled to the bending motion of the methyl group relative to the ring, and correctly assigns the (*R*)-configuration to the molecule.

An extensive study has focused on terpenes with structures related to pinane, camphor [8], and limonene [9]. The in-phase dual circular polarization (DCP₁) ROA spectra and the normalized CIDs are presented for 14 compounds. Correlations between ROA features and structural elements of the molecules are discussed. The study clearly demonstrates the advantage of the back-scattering measurements, which for theoretical reasons should be about three times as intense as the normal right-angle incident circular polarization (ICP) measurements.

The Raman and ROA spectra of the hydrochloride salts of four medically applied ephedrine molecules in aqueous solution have been compared in the 700–1700 cm^{-1} region. The salts of (1*S*,2*R*)-ephedrine [10], (1*S*,2*R*)-norephedrine [11], (1*S*,2*S*)-pseudo-ephedrine [12] and (1*S*,2*S*)-norpseudoephedrine [13] show some bands which with a high degree of probability can be used as configurational ROA markers. For example, a band near 840 cm^{-1} (strongly positive for [11–13]) reflects the chirality at C-1 and probably arises from the symmetric CCO stretch, while a band near 910 cm^{-1} , which is strongly negative in [11 and 12] arises from the antisymmetric CCO stretch at C-1. The chirality of the $\text{C}^*\text{HCH}_3(\text{NH}_2\text{R}^+)$ moiety at C-2 may be reflected by the bands of the antisymmetric methyl deformation at 1450 cm^{-1} , as they are oppositely signed in the two (1*S*,2*R*)-ephedrines (both positive) and the two (1*S*,2*S*)-pseudoephedrines (both negative).

Crystals

Optical activity in crystals is not only the effect of a single molecule but contains also the effects of a large

array of similar entities. This is why the crystal ROA is about one order of magnitude larger and one can measure vibrations which cannot be observed in solutions or neat liquids. But one has to be careful not to observe artifacts produced by the linear birefringence of the crystals. An interesting class of crystals are the cubic crystals of the sodium halogenates. These are composed of achiral subunits that form a chiral array and therefore crystallize in enantiomorphic crystals, belonging to space group T^+ ($P2_13$). In the ROA spectra of sodium chlorate and bromate, longitudinal and transverse optical F phonons could be resolved. As an example, the depolarized right-angle scattering Raman and ROA spectra of sodium bromate are shown in **Figure 2**. At a resolution of 1.8 cm^{-1} the non-degenerate longitudinal (LO) and doubly degenerate transverse (TO) optical modes can be observed separately. The observed signs can be attributed to one of the two possible chiral arrays.

Biochemical Applications

One of the great advantages of Raman spectroscopy over IR spectroscopy is the ready applicability of water as a solvent. This is of course very important in biochemistry, where the compounds to be studied are, preferably, to be dissolved in water, as that is their natural medium. Nearly all biochemical compounds are chiral, so it is reasonable to study them not only by Raman spectroscopy but also by ROA, where additional features can be observed or resolved.

Carbohydrates

High quality spectra of carbohydrates can be measured in saturated aqueous solution, exhibiting clear bands that can be readily attributed to the orientation of OH substituents, anomeric preference and the conformation of exocyclic CH_2OH groups. As 15 monosaccharides (e.g.

Figure 2 Depolarized right-angle scattering Raman and ROA spectra for the lattice vibrations of (+)- NaBrO_4 (—) and (–)- NaBrO_4 (·····), both 1.8 cm^{-1} resolution. Reproduced with permission of John Wiley & Sons from Lindner M, Schrader B, and Hecht L (1995) *Journal of Raman Spectroscopy* 26: 877. Copyright 1995 John Wiley & Sons.

arabinose, glucose, xylose, galactose and mannose) have been examined, the conclusion that the ROA features reflect local stereochemical details seems to be based on enough material to be reliable.

In di- and polysaccharides ROA can probe the type and conformation of the glycosidic link. Early investigations on D-maltose [14] show a glycosidic couplet at $890\text{--}960\text{ cm}^{-1}$ (centred at about 917 cm^{-1}) similar to that of D-glucose [15]. It is concluded that for the $\alpha(1 \rightarrow 4)$ glycosidic link the couplet is positive at lower and negative at higher wavenumbers.

ROA observed at lower wavenumbers is also valuable for the determination of configuration. Compared with D-galactose, the disaccharide D-maltose and the polysaccharide laminarin [16] show a large ROA couplet centred at about 430 cm^{-1} . The configuration giving rise to a couplet that is negative at low, but positive at high wavenumbers is a β -glycosidic link (e.g. D-cellobiose, laminarin), whereas an α -glycosidic link (D-maltose) is positive at low, but negative at high wavenumbers.

An extension of the investigations to the disaccharides D-maltose, D-maltose-*O*- d_8 , D-cellobiose, D-isomaltose,

D-gentobiose, D-trehalose and α -D-cyclodextrin confirms these results.

In cyclodextrins (CDs), conformational flexibility is studied by ROA. Using maltoheptose, β -cyclodextrin [17] and its derivatives with double or triple *O*-methylated sugar rings, an order of increasing flexibility of the CD ring could be established. Increases in couplet signal strength centred at $\sim 915\text{ cm}^{-1}$ are interpreted in terms of a reduction in conformational flexibility of the cyclodextrin ring. Maltoheptose (linear) is expected to be the most flexible of the compounds, as found in the investigation. Strong complexation of a guest molecule in the CDs also lowers flexibility.

Other polysaccharides studied by ROA are laminarin [16] and pullulan [18]. Laminarin, which is a $\beta(1 \rightarrow 3)$ linked polymer of D-glucose, adopts a triple helix conformation. This is concluded by comparison with the ROA of the compound that corresponds to laminarin's dimer subunit, D-laminaribiose. Pullulan is a linear polymer of D-glucose, consisting of D-maltotriose units connected through $\alpha(1 \rightarrow 6)$ glycosidic links. It adopts a random coil structure in aqueous solution, as can be deduced by the similarity of its ROA spectrum to that of D-maltotriose.

Amino Acids

ROA spectra of L-(*S*)- as well as D-(*R*)-alanine [19] together with a detailed *ab initio* vibrational analysis of

their zwitterionic structure at the 6-31G and the 6-31G* level have been reported. Though in the Raman spectra

[18]

dependence on pH is clearly visible, the ROA spectra are not influenced by H^+ concentration. It is concluded from the fact that VCD spectra *do* respond to pH variation that ROA is more directly coupled to chirality and thus can yield more reliable information about absolute configuration.

[19]

The simple amino acids L-serine, L-cysteine, L-valine, L-threonine and L-isoleucine have been studied in aqueous solution by backscattering, using the spectral range from 600 to 1600 cm^{-1} . Bands originating in C_{α}^*H deformation and the symmetric CO_2^- stretch provide the best signatures for stereochemical studies. The ROA of the former vibration is positive for all acids studied and that for the latter negative. Isoleucine is an exception as it shows a nearly featureless ROA spectrum. The reason may be that it exists as an equal mixture of two rotamers in water.

Peptides and Proteins

ROA spectra have proven to be of great value to study the secondary structure of proteins. By examining the four different regions that contain the stretching vibrations of the backbone of proteins (the extended amide III region, the sidegroup and amide II region, and the amide I region), their α helix, β sheet, reverse turn and random coil content can quite readily be determined. This approximate division is shown in the lysozyme part of **Figure 4** (see below). Of course some sidegroups can also be observed by their Raman active vibrations, e.g. lysozyme and α -lactalbumin show tryptophan bands.

As a model for the peptide backbone *N*-acetyl-*N'*-methyl-L-alaninamide (NANMLA) [20] was subjected to a detailed ROA analysis. Its experimental spectrum was compared with the calculated spectra of nine different conformations. Both geometry optimizations and vibrational analyses using *ab initio* methods and the basis set 6-31G* were conducted on these conformers. As a result of these calculations the four conformers C_5 , $C_{7,eq}-C_5$, $C_{7,eq}$ and α_R were found to play an important role in the room temperature equilibrium. These four conformers are characterized by torsion angles of $\phi = -157, -85, -99$ and -60° , and of $\psi = 159, 136, 79$ and -40° , respectively; here ϕ is the $OC-NH-C^*-CO$ backbone torsional angle and ψ is the $HN-C^*-CO-HN$ angle. Though the comparison between experimental and calculated spectra does not give unambiguous results, it gives strong hints that the predominant conformer in H_2O , D_2O and chloroform solution is the $C_{7,eq}-C_5$ conformer and that the α_R conformer is a minor component in H_2O and chloroform solutions, whereas the $C_{7,eq}$ conformer could be present in small amounts in D_2O solution.

[20]

The dipeptide L-alanyl-L-alanine [21] shows bands similar to the spectrum of L-alanine. In water, bands between 850 and 950 cm^{-1} can be attributed to the $C^{\alpha}-N$ stretch, symmetric CO_2 bend and the $C^{\alpha}-C(O)$ stretch. In addition, the dipeptide shows a negative ROA band at $\sim 1270\text{ cm}^{-1}$ and a large positive ROA at $\sim 1340\text{ cm}^{-1}$. These vibrations occur in all known protein ROA spectra. According to newer investigations, the Raman band associated with the former effect is not only the amide III vibration but a superposition of three modes, of which only the C_C-H^I deformation (which is the first of two possible

Figure 3 Bovine seminal ribonuclease, disulfide bridges shown in black. Structure drawn with HyperChem 5.0 from PDB entry 1BSR of Mazzarella L, Capasso S, Demasi D, Di Lorenzo G, Mattia CA, and Zagari A (1993) *Acta Crystallographica Section D* 49: 389; The Protein Data Bank: Bernstein FC, et al. (1977) *Journal of Molecular Biology* 112: 535–542.

orthogonal C_C-H deformations) contributes to the ROA. The positive ROA at $\sim 1340\text{ cm}^{-1}$ arises from the N–H in-plane deformation coupled to the C_N-H^{II} deformation.

[21]

Looking at the ROA spectra of α helical and several unordered poly(L-lysine) preparations of increasing relative molecular mass (M_r), one finds not only bands at ~ 931

and 943 cm^{-1} , but also a strong sharp positive ROA band at $\sim 1340\text{ cm}^{-1}$, which belongs to loops with a local order of a 3_{10} helix connecting regions of a helices. This feature, which is quite small at lower M_r (26 000), becomes more prominent at increasing M_r and becomes the dominant feature in a 268 000 Da protein, thus showing the 3_{10} helix content growing at the expense of the α helix.

Bovine serum albumin, which has a high α helix but no β sheet content, shows a strong positive band at 1340 cm^{-1} , probably connected to surface loop features forced mainly by its 17 disulfide linkages. This prevents coupling of modes in this spectral region to other parts of the molecule and now the localized ‘amide III’ modes strongly resemble the vibrations in L-alanyl-L-alanine.

Figure 4 Backscattered Raman and ROA spectra of native hen egg-white lysozyme (top pair) and of native bovine ribonuclease A (bottom pair), both in acetate buffer at pH 5.4. Reprinted with permission from Wilson G, Hecht L, and Barron LD (1996) *Biochemistry* 35: 12518–12525. Copyright 1996 American Chemical Society.

The large globular protein ovalbumin, which has only a few disulfide bridges, lacks this large ROA feature.

α -Lactalbumin contains α helices as well as β sheet regions, and therefore shows bands at the corresponding wavenumbers in the 1020–1060 cm^{-1} part of the C^{α} –N stretch region. Large changes are induced in the extended amide III region as the hydrogen on nitrogen is replaced by deuterium, simplifying the spectra and thus allowing for easier identification of the remaining features.

It has been shown that ROA can detect residual amounts of structure in mainly unfolded proteins. Investigations on hen egg-white lysozyme and bovine ribonuclease A show that both proteins lose their natural structure to quite a large extent on reducing all the disulfide bonds (shown in **Figure 3** for ribonuclease A) in citrate buffer. The Raman and ROA spectra of the native proteins are shown in **Figure 4**. Lysozyme and ribonuclease A are known to contain both large α helix and β sheet regions, but on denaturation by reduction the two proteins behave differently. Whereas unfolded lysozyme loses nearly all of its structure at room temperature and

only regains about 20 % of its α helix content when cooled to 2 °C, ribonuclease A still has about 50 % of its secondary structure at room temperature.

A further study of native hen egg-white lysozyme, using the pH 5.4 buffer solution spectra of the molecule in the temperature range 2–50 °C, revealed a new cooperative transition at ~ 12 °C. A detailed analysis shows the protein's adoption of a more rigid structure, where tertiary loops and tryptophan sidegroups lose their residual mobility.

The human α_1 -acid glycoprotein orosomucoid shows ROA bands that are characteristic of a high β -sheet content. It is to be expected from this single reported example that the ROA spectra of glycoproteins will yield valuable information about the conformation of the molecule, especially upon the mutual influence of the different protein and carbohydrate parts.

Another human protein that has been studied by ROA methods is the human serum albumin. Most prominent features in its ROA spectrum are bands that arise from the large α helix content and the already discussed strong positive band at ~ 1340 cm^{-1} which is characteristic for loop structures with local order of a 3_{10} helix. The latter band decreases to ~ 40 % on reducing the pH to 3.4, where the molecule assumes its F state, which is a mildly denaturated form created by dissociation of the two halves of the heart-shaped molecule. These findings may be explained by a loss of rigidity of the molecule and are in accordance with X-ray analyses of the crystalline state and derived structure proposals for the F state.

Nucleosides, Nucleotides and Nucleic Acids

Pyrimidine nucleosides have been studied in backscattering. Unlike in normal Raman spectroscopy, where the sugar moiety only gives rise to weak signals, ROA detects signals of comparable intensity as well from the sugar as from the interaction of the sugars with the bases, but there are no signals from nearly achiral vibrations localized in the planar base rings. Of great diagnostic value are signals arising from the stretching at the $\text{C}(1')\text{--N}(1)$ glycosidic bond. These signals (~ 1200 , 1230, 1380 and 1400 cm^{-1}) have opposite signs for α - and β -thymidine [22].

[22]

Figure 5 Backscattered Raman ($I^R + I^L$) and ROA ($I^R - I^L$) spectra of poly(rA) in H_2O (bottom) and D_2O (top). Reprinted with permission from Bell AF, Hecht L, and Barron LD (1997) *Journal of the American Chemical Society* 119: 6006–6013. Copyright 1997 American Chemical Society.

Of the three nucleotides adenylic acid, uridylic acid and cytidylic acid the three single-stranded polyribonucleotides as well as two double-stranded nucleotides were examined by ROA spectroscopy. Three regions were especially valuable for the analysis: 1550–1750 cm^{-1} (called the base stacking region), 1200–1550 cm^{-1} (sugar–base coupling region) and 950–1150 cm^{-1} (sugar–

phosphate backbone region). As the name suggests, the first region reflects base stacking. The second shows the orientation of the sugar and base rings. The third reflects the conformation of the sugar ring, even though the backbone may also be involved. Typical spectra in H_2O as well as in D_2O are shown in **Figure 5**. These spectra of polyadenylic acid show two large negative peaks in the

sugar base region in the ROA. As expected, the base-dependent signatures lose much of their intensity on exchange with D₂O, whereas the sugar phosphate backbone region remains virtually unaltered.

Other Applications

Apart from probing molecular conformation and configuration, ROA has been employed in a couple of other interesting tasks.

The applicability of ROA for the determination of enantiomeric excess in mixtures of chiral enantiomers has been exploited. Using the test compound α -pinene an accuracy of 0.1 % enantiomeric excess (ee) was achieved.

The possibility of observing Raman optical activity from chiral surfaces has been mentioned and a theory for the generation of second-harmonic optical activity (SHOA) from chiral surfaces and interfaces has been derived.

Even theoretical aspects may be attacked by ROA spectroscopy. In benzene derivatives containing heteroatoms the question arises as to whether Rydberg transitions centred on the heteroatom are involved in the production of Raman spectra. Using a comparison between the polarized and depolarized ROA spectra, this contribution of Rydberg transitions could be detected in 1-phenylethanol and 1-phenylethylthiol, as large deviations from the factor of 2 in the ratio of polarized to depolarized spectra were found.

Protein folding is an area of much recent activity. It has been shown by ROA that water acts as lubricant in helix coil unfolding. Extremely fast conformational fluctuations seem to occur with a frequency of about 10^{12} s^{-1} . These turnover rates, which are close to the theoretical limit of kinetics, could only be observed owing to the very short time scale ($\sim 10^{-14} \text{ s}$) of Raman techniques.

The very high quality of ROA spectra makes it possible even to obtain difference ROA spectra of substances at two different temperatures. By this method the pre-melting of poly(rA)·poly(rU) was monitored. The compound, which has an A-type double helical structure, shows qualitatively the same ROA spectrum at both 20 and 45 °C, while the intensities of the bands are lowered. From the fact that the difference spectrum is similar to the ROA spectra at both temperatures, it is concluded that the same average structure is maintained throughout all temperatures in the range examined. The investigation demonstrates the usefulness of the new technique to probe the dynamics of nucleic acids in aqueous solution.

Introduction

The past decade has seen a vast increase in publications about Raman optical activity (ROA), so that two articles are really necessary to cover the areas of applications. One is on small molecules (including small biological molecules as amino acids, dipeptides, and small sugars) and the other is on macromolecules (mainly biological in nature). This large increase can be attributed mainly to the availability of high-quality commercial ROA instrumentation, thus promoting ROA technology from an area of technically highly skilled specialist to a near-routine method. This article surveys the macromolecular applications of ROA.

Biochemical Applications

One of the great advantages of Raman spectroscopy over infrared spectroscopy is the ready applicability of water as a solvent. This is of course very important in biochemistry, where the compounds to be studied have preferably to be dissolved in water, as this is their natural medium. This fact facilitates the study of compounds with complete control of pH and salt content of the solvent. Nearly all biochemical compounds are chiral, so it is reasonable to study them not only by Raman spectroscopy but also by ROA, where additional features can be observed or resolved.

Carbohydrates

The spectra of carbohydrates can be measured with high quality in saturated aqueous solution, exhibiting clear bands that can be readily attributed to the orientation of

OH substituents, anomeric preference, and the conformation of exocyclic CH_2OH groups.

The type and conformation of the glycosidic link can be probed by ROA. The glycosidic couplet found between 890 and 960 cm^{-1} and centered at 917 cm^{-1} is positive at lower and negative at higher wave numbers for the $\alpha(1\text{--}4)$ glycosidic link.

In cyclodextrins (CDs), evidence for conformational flexibility could be found using ROA. In a study of maltoheptose, β -CD [1], and its derivatives with two or three ring hydroxyl groups methylated, an order of increasing flexibility of the CD ring could be established. Increases in the couplet signal strength centered at $\sim 915\text{ cm}^{-1}$ were interpreted in terms of a reduction in conformational flexibility of the CD ring. Maltoheptose (linear) is expected to be the most flexible of the compounds, as found in the investigation. Good complexation of a guest in the CDs also lowers flexibility.

Other polysaccharides studied by ROA are laminarin [2] and pullulan [3]. Laminarin, which is a $\beta(1\text{--}3)$ -linked polymer of D-glucose, adopts two articles are really necessary to cover the areas of applications. One is on triple helix conformation. This is concluded by comparison with the compound that corresponds to the pullulan dimer subunit, D-laminaribiose. Pullulan is a linear polymer of D-glucose, consisting of D-maltotriose units connected through $\alpha(1\text{--}6)$ glycosidic links. It adopts a random coil structure in aqueous solution, as can be deduced by the similarity of its ROA spectrum to that of D-maltotriose.

Peptides and Proteins

ROA spectra have proven to be of great value to study the secondary structure of proteins. By examining the four different regions containing the vibration of the backbone of proteins (the extended amide III region, the sidegroup and amide II region, and the amide I region), their

α -helix, β -sheet, reverse turn, and random coil content can quite readily be determined. This approximate division is shown in the lysozyme part of **Figure 2** (see the following text). Of course some sidegroups can be observed by their Raman active vibrations, for example, lysozyme and α -lactalbumin showing tryptophan bands.

As a model for the peptide backbone, *N*-acetyl-*N'*-methyl-L-alaninamide (NANMLA) [4] was subjected to a detailed ROA analysis. Its experimental spectrum was compared to the calculated spectra of nine different conformations. Both geometry optimizations and vibrational analyses using *ab initio* methods and the basis set 6-31G* were conducted on these conformers. As a result of these calculations, the four conformers C_5 , $C_{7,eq}$ - C_5 , $C_{7,eq}$, and α_R were found to play an important part in the room temperature equilibrium. These four conformers are characterized by torsion angles of $\varphi = -157^\circ$, -85° , -99° , and -60° , and of $\psi = 159^\circ$, 136° , and 79° , and -40° respectively; here φ is the OC-NH-C*-CO backbone torsional angle and ψ is the HN-C*-CO-HN angle. Although the comparison between experimental and calculated spectra does not give unambiguous results, it gives strong hints that the predominant conformer in H₂O, D₂O, and chloroform solution is the $C_{7,eq}$ - C_5 conformer and the α_R conformer is a minor component in the H₂O and chloroform solution, whereas the $C_{7,eq}$ conformer could be present in small amounts in the D₂O solution.

Looking at the ROA spectra of α -helical and several unordered poly(L-lysine) preparations of increasing relative molecular mass (M_r), one not only finds bands at ~ 931 and 943 cm^{-1} , but also finds a strong sharp positive ROA band at $\sim 1340\text{ cm}^{-1}$, which belongs to loops with a local order of a 3_{10} helix connecting regions of α -helices. This feature, which is quite small at lower M_r (26 000), becomes more prominent at increasing M_r and becomes the dominant feature in a 268 000 Da protein, thus showing the 3_{10} helix content growing at the expense of the α -helix.

Bovine serum albumin, which has a high α -helix but no β -sheet content, shows a strong positive band at 1340 cm^{-1} , probably connected to surface loop features forced mainly by its 17 disulfide linkages. This prevents coupling of modes in this spectral region to other parts of the molecule and now the localized 'amide III' modes strongly resemble the vibrations in L-alanyl-L-alanine. The large globular protein ovalbumin, which has only a few disulfide bridges, lacks this large ROA feature.

It has been shown that ROA can detect residual amounts of structure in mainly unfolded proteins. Investigations on hen egg white lysozyme and bovine ribonuclease A show that both proteins lose their natural structure on reducing all the disulfide bonds (shown in **Figure 1** for ribonuclease A) in citrate buffer to quite a large extent. The Raman and ROA spectra of the native proteins are shown in (**Figure 2**). Lysozyme and ribonuclease A are known to contain large α -helix and β -sheet regions, but on denaturation by reduction the two proteins behave differently. Whereas unfolded lysozyme loses nearly all of its structure at room temperature

Figure 1 Bovine seminal ribonuclease, structure drawn with GaussView 4 from PDB entry 1BSR. Mazzarella L, Capasso S, Demasi D, Di Lorenzo G, Mattia CA, and Zagari A (1993) Bovine seminal ribonuclease: structure at 1.9 Å resolution. *Acta Crystallographica* Section D 49: 389; The Protein Data Bank: Bernstein FC, Koetzle TF, Williams GJB, et al. (1977) The protein data bank: A computer-based archival file for macromolecular structures. *Journal of Molecular Biology* 112: 535–542.

and only regains $\sim 20\%$ of its α -helix content when cooled to 2°C , ribonuclease A has still $\sim 50\%$ of its secondary structure at room temperature.

The resonance ROA spectrum of horse heart cytochrome *c* (**Figure 3**, the similar human cytochrome *c* structure shown in **Figure 4**) revealed a distinct spectral signature pattern due to resonance enhanced skeletal porphyrin vibrations, more pronounced than any contribution from the protein backbone. The features in the spectrum could be fully assigned.

In viral coat proteins, a sharp tryptophan ROA band at 1550 cm^{-1} is attributed to the W3-type vibration of the indole ring. The exact wavenumber of W3 correlates with the magnitude of the torsion angle $\chi^{2,1}$ defined by the three bonds $\text{C}_2=\text{C}_3-\text{C}_\beta-\text{C}_\alpha$. It can thus serve as the monitor for the absolute stereochemistry of the tryptophan side chain, but the sign is only available from ROA spectra. In those strains of filamentous bacterial viruses that contain a single tryptophan in the major coat proteins, namely, M13 and IKE, a sharp *positive* ROA band appears at $\sim 1554\text{ cm}^{-1}$ similar to one observed in most native globular proteins containing tryptophans. Although generally similar to the other three ROA spectra, the main features of which reflect the extended helix fold containing roughly equal amounts of hydrated and hydrophobic α -helix, the $\sim 1550\text{ cm}^{-1}$ tryptophan W3 ROA band of pH 75 is *negative*. This suggests that the absolute stereochemistry of the indole ring relative to the

plane defined by $\text{C}_3-\text{C}_\beta-\text{C}_\alpha$ in pH 75 is quasienantiomeric to that in M13 and IKE. The parent W3 Raman band wavenumbers are $\sim 1555\text{ cm}^{-1}$ for M13 and IKE that correspond to a value for the torsion angle magnitude $\chi^{2,1}$ of $|105^\circ|$, and $\sim 1550\text{ cm}^{-1}$ for pH 75 corresponding to $|93^\circ|$.

The structures of intact glycoproteins are quite difficult to characterize using the standard techniques of structural biology (X-ray crystallography and NMR spectroscopic techniques). Although the carbohydrate content of the bovine α_1 -acid glycoprotein (AGP) represents 45% of its molecular weight, only the structure of the protein part could be deduced to some extent by these methods. Using ROA, both polypeptide and carbohydrate structures of the intact glycoprotein could be studied. It was found by comparison of the ROA spectra (**Figure 5**) that the structure of the *N*-linked pentasaccharide core contains the structure of *N,N'*-diacetylchitobiose, which means that the first two glycosidic links after the *N*-links to asparagine are of the $\beta(1-4)$ -type. The human AGP orosomucoid shows ROA bands characteristic of a high β -sheet content.

Ab initio simulations of vibrational spectra of proteins are becoming more and more important as computers and theoretical methods can tackle larger problems as the speed of calculations is increasing by a power of 10 roughly every 3 years. ROA of poly-L-proline has been calculated with Hartree-Fock (HF) and density functional theory

Figure 2 Backscattered Raman and ROA spectra of native hen egg white lysozyme (top pair) and of native bovine ribonuclease A (bottom pair, both in acetate buffer at pH 5.4). Reproduced with permission from Wilson G, Hecht L, and Barron LD (1996) Residual structure in unfolded proteins revealed by Raman optical activity. *Biochemistry* 35:12518–12525. Copyright 1996 American Chemical Society.

(DFT) methods on different theoretical levels with solvent correction and the results compared to experimental data. Analysis of the spectra indicates that the conformer populations of the two proline ring conformers in the sample are each $\sim 50(\pm 15)\%$.

Vibrational ROA spectra of three seed storage or gluten proteins of wheat were measured to gain new insights into their solution structures. α -Gliadin contains a considerable amount of hydrated α -helix, most of which probably lies within a relatively structured C-terminal domain. Smaller quantities of β -structure and poly(L-proline) II (PPII) helix were also identified. Addition of methanol was found to increase the α -helix content at the expense of some of the β - and PPII structures. In comparison, ω -gliadin and the T-A-1 peptide (a 30-kDa peptide from the high molecular weight glutenin subunit (HMW-GS) Dx5) were found to consist of large amounts of well-defined PPII structure with some β turns but no α -helix.

Another important structural element in proteins, the poly(L-proline) II (PPII) helix, can also be detected readily by ROA. Although this helix type is named after the conformations of L-proline polymers, it can be found in the structure of many other proteins. A recent ROA study of alanine oligopeptides (Ala_m , $n=2-5$, and Acetyl-Orn₂Ala₇Orn₂-Amide or Acetyl-OOAAAAAA AOOA mide is a protected Undekapeptide, Containing 4 ornithine and 7 alanine subunits) in aqueous solution confirmed the previous assignment of positive ROA at $\sim 1319\text{ cm}^{-1}$, together with weak positive ROA at $\sim 1675\text{ cm}^{-1}$, to PPII. Another band at $\sim 1310\text{ cm}^{-1}$ is also diagnostic of PPII. This band is sensitive to pH since in Ala₄ one can find the peak at ~ 1312 , ~ 1315 , and 1325 cm^{-1} at low, neutral, and high pH, respectively.

The infectious agents of a family of neurodegenerative diseases, to which among others scrapie belongs, are the prion proteins. Inspection of the ovine prion protein by ROA reveals a characteristic band at 1315 cm^{-1} , characteristic for a poly(L-proline) II (PPII) helix. This band is missing in a related protein, which lacks some N-terminal amino acids.

ROA investigation on the protein folding of the full-length recombinant murine prion protein PrP²³⁻²³¹ at neutral pH examines the influence of divalent copper and manganese ions. Such processes are of interest for the possibility of scrapie PrP formation. It was found that adding Cu^{2+} after refolding results in the loss of the hydrated α -helix, so that the total α -helix content of the protein drops from 25% to 18%, whereas the protein's structure becomes almost completely disordered (α -helix content $\sim 5\%$) when the ions are present during the refolding process. In contrast, when the protein is refolded in the presence of Mn^{2+} , ROA (Figure 6) indicates that the α -helix content is even augmented to $\sim 30\%$.

Poly(L-lysine) serves as a model for proteins in the β -sheet conformation. Using the molecule's ROA spectrum, its α -helix $\Rightarrow$ β -sheet transition could be monitored as a function of temperature in H₂O and D₂O (Figure 7). Poly(L-lysine) in the β -sheet state contains many bands quite distinct from those observed in the α -helix and disordered states. This facilitated the study of the transition, which revealed no significant population of a disordered intermediate backbone state but did reveal some intermediate side chain structure not present in the initial or final states.

The application of principal component analysis (PCA) to ROA spectra produced a representation of the structural relationships between the polypeptide and protein states studied. The quality of ROA spectra nowadays is high enough to allow for multivariate analysis to separate proteins into seven structure classes: all α , mainly α , $\alpha\beta$, mainly β , all β , mainly disordered/irregular, and all disordered/irregular.

Of the three nucleotides adenylic acid, uridylic acid, and cytidylic acid the three single-stranded polyribonucleotides as well as two double-stranded nucleotides were examined by ROA spectroscopy. Three regions were especially valuable for the analysis: 1550–1750 cm^{-1} (called the base stacking region), 1200–1550 cm^{-1} (sugar–base coupling region), and 950–1150 cm^{-1} (sugar–phosphate backbone region). As the name suggests, the first region reflects base stacking. The second shows the orientation of the sugar and base rings. The third reflects the conformation of the sugar ring, even though the backbone also may be involved. Typical spectra in H_2O as well as in D_2O are shown in **Figure 8**. These spectra of polyadenylic acid show two large negative peaks in the sugar–base region in the ROA. As expected, the base-dependent signatures lose much of their intensity on exchange with D_2O , whereas the sugar–phosphate backbone region remains virtually unaltered.

Other Applications

Apart from probing molecular conformation and configuration, ROA has been employed in a couple of other tasks.

Protein folding is an area of much recent activity. In an early work, it could be shown by ROA that water acts as lubricant in helix coil unfolding. Extremely fast conformational fluctuations seem to occur with a frequency of $\sim 10^{12}$ per second. These turnover rates, which are close to the theoretical limit of kinetics, could only be observed due to the very short timescale ($\sim 10^{-14}$ s) of Raman techniques.

Not only single proteins can be investigated by ROA but also parts of whole bacteria. Intense ROA bands were observed from the L-type straight flagellar filaments of a mutant of *Salmonella typhimurium*. The three positive major bands at 1653 cm^{-1} in the amide I

region, 1317 cm⁻¹ in the amide III region, and 949 cm⁻¹ in the skeletal vibrational region are the contributions from the amide groups in the main chain of the protein. On disassembly of the flagella to the flagellin monomer by heating and fragmentation of the

flagellar filament by ultrasonic treatment, the intense ROA bands disappear, which means that the bands, which are one order of magnitude larger than those of monomeric α -helical proteins, are characteristic of the assembly.

Introduction

Raman optical activity (ROA), which is most often measured as the dimensionless circular intensity difference (CID or better DCID, $[I_r - I_l]/[I_r + I_l]$), is a very small effect that can be easily obscured by artifacts. The first ROA spectrometers were scanning Raman spectrometers modified by adding devices to modulate the polarization of the exciting laser beam. Therefore, very few spectra were measured before the advent of a new generation of spectrometers. Two main technical advances made the construction of these sensitive instruments possible: first, the development of multichannel detectors culminating in back-thinned charge-coupled devices (CCDs), which are practically ideal light detectors with quantum efficiencies of approximately 80% at the wavelength of peak sensitivity; second, the development of the holographically manufactured line filter. The first improvement shortened the time of measurement to approximately 20 min for pure samples and allowed the measurement of dilute samples in a few hours; the second allowed the replacement of multiple monochromators by a single polychromator with much higher optical throughput. As these spectra are very much improved, mainly the literature of the past 15 years is covered in this review. The interested reader is

directed to earlier reviews given in the references for historic data. Nowadays even commercial instruments are available, vastly increasing the number of papers on ROA (which made necessary the division of the former single ROA applications article in two).

To be useful for structural determinations, ROA spectra have to be compared to calculated spectra. Models confined to special functional groups or semiempirical calculations have been of limited success for this purpose. During the past decade, *ab initio* studies have become possible. These calculations, especially the time-consuming ones with large basis sets or even with the inclusion of configurational interaction, allow for useful derivation of absolute configuration or even conformation. Density functional theory (DFT) calculations of vibrational Raman optical activity (VROA) reduced the calculation times and increased the achievable accuracy. An extensive investigation of the dependence of the scattering intensity difference of right and left circularly polarized light observed in VROA on the choice of basis set and exchange–correlation has been published. The use of DFT even made possible the time-consuming calculation of solvent effects on ROA spectra using the polarizable continuum model.

Stereochemistry of Small Chiral Molecules

One of the simplest chiral molecules one can imagine is bromochlorofluoromethane [1]. As it is a liquid that until now has only been obtained as an enriched but not pure substance, no crystal structure suitable to deduce the absolute configuration could be obtained. It was therefore a great success for ROA, together with *ab initio* calculations, that it is possible to deduce the absolute conformation of this molecule by comparing experimental and calculated spectra. **Figure 1** shows the depolarized Raman and ROA spectra of CHFCIBr (36% enantiomeric excess) together with the calculated spectrum of the (*R*)-enantiomer. Seven of nine ROA band calculations arrive at the right sign.

Instrumental advances in ROA, combined with quantum chemical computations, made it even possible to determine the absolute configuration of (*R*)-[$^2\text{H}_1$, $^2\text{H}_2$, $^2\text{H}_3$]-neopentane (**Figure 2**). This saturated hydrocarbon represents the archetype of all molecules that are chiral as a result of a dissymmetric mass distribution. It is chemically inert and cannot be derivatized to yield molecules that would reveal

Figure 1 Depolarized Raman (upper curve) and ROA (lower curve) spectra of $(-)$ -CHFCIBr together with the calculated spectra (middle curves) for the (R) -isomer. Reproduced from Costante J, Hecht L, Polavarapu PL, Collet A, and Barron LD (1997) *Angewandte Chemie International Edition in English* 36: 885–887, with permission.

the absolute configuration of the parent compound. Diastereomeric interactions with other molecules, optical rotation, and electronic circular dichroism (ECD) are, in contrast to the aforementioned case of bromochlorofluoromethane, not expected to be measurable. Vibronic effects in the vacuum ultraviolet circular dichroism might reveal that the molecule is chiral, but the presence of nine rotamers would make it extremely difficult to interpret the

spectra, because the spatial arrangement of the rotamers' nuclei resembles that of the enantiomers. Impossible by other techniques, determination of the absolute configuration of (R) - $[^2\text{H}_1, ^2\text{H}_2, ^2\text{H}_3]$ -neopentane by ROA, therefore, was extremely difficult, and shows the boundary of the achievable by this spectroscopic technique.

Ab initio calculations of the vibrational Raman and ROA spectra of D-lactic acid, D-lactate, and D-glyceraldehyde have been carried out at the linear response self-consistent field level for various conformations. Using Dunning's basis sets cc-pVDZ and aug-cc-pVDZ, it has been found that, unlike the information obtained by normal Raman spectroscopy, the VROA parameter of the stretching vibration of the carbonyl group is shown to be a promising parameter for structural investigations because it changes sign when a short internal hydrogen bond $\text{O}-\text{H} \cdots \text{O}=\text{C}$ is formed.

The well-known molecule $(2R,3R)$ -(+)-tartaric acid [2] has been studied as its both d_0 and d_4 isotopomers. As small molecules are less demanding concerning computation time, the molecule could be studied at three theoretical levels: *ab initio* calculations using the 6-31G, 6-31G*, and DZP basis sets were performed and compared with the experimental spectra. The molecule was found to exist as a single conformer in aqueous solution, that is, the conformation with the carboxylic groups *trans* to each other [2].

A comparison between vibrational circular dichroism (VCD) and ROA spectra of the four structurally similar molecules *trans*-pinane [3], *cis*-pinane, α - and β -pinene together with theoretical calculations show that the ratio of the parent technique (infrared (IR) or Raman spectroscopy) to its chiral counterpart is by a factor of 3 in favor of ROA. This advantage is unfortunately canceled by the somewhat more difficult method of measurement. Quantitative comparisons enlighten the supposition that VCD and ROA are highly complementary nonredundant stereochemical techniques.

The experimental and calculated (6-31G* basis set) spectra of (R) -(+)-dimethyloxirane [4] in the

Figure 2 Determination of the absolute configuration of chiral deuterated neopentane. Reproduced with permission from the homepage of J. Haesler. See: Haester J, Schindelholz I, Riguet E, Bochet CG, and Hug W (2007) Absolute configuration of chiral deuterated neopentane. *Nature* 446: 526–529.

200–1500 cm^{-1} region agree for the majority of bands. Depolarized, polarized, and ‘magic angle’ Raman and ROA spectra have been measured. By setting the transmission axis of the analyzer at the ‘magic angle’ of $\pm 35.26^\circ$ to the vertical, only contributions from the

electric dipole–magnetic dipole polarizability are present in the ROA spectra. As expected, calculations at higher theoretical levels give better results for the calculation of normal modes, but for the calculation of the polarizability derivatives, they do not show any remarkable

advantage. This is very important for practical reasons, as one can use the less time-consuming calculations for the calculations of ROA.

Methyl torsion ROA of *trans*-2-dimethyloxirane has been compared to that of *trans*-2,3-dimethylthiirane [5]. Torsion of the two methyl groups in these molecules can occur as in-phase and out-of-phase combinations. The former can be observed as a very weak and broad Raman band at $\sim 200\text{ cm}^{-1}$ in the dimethyloxirane with positive ROA of medium size, whereas it is observed at $\sim 220\text{ cm}^{-1}$ as a shoulder in the spectrum of the dimethylthiirane with large positive ROA. Contrary to the dimethyloxirane spectra, the dimethylthiirane spectra also contain the out-of-phase torsion: it shows up as a medium-size Raman band at $\sim 245\text{ cm}^{-1}$ with zero or small negative ROA. This is in good agreement with *ab initio* calculations and even with the old inertial model for methyl torsions.

From the ROA of *trans*-2,3-dimethylthiirane, the absolute configuration has been determined. Its experimental spectrum is very similar to that calculated (*ab initio*, basis set 6-31G*) for the 2*R*,3*R*-isomer [5] with best agreement in the skeletal vibration region.

The vibrational spectrum of (*S*)-3-methylcyclopentanone [6] has been calculated on the 6-31G and on the 6-31G** level, whereas ROA has only been predicted on the 6-31G**/6-31G and on the 6-31G level. The calculations with the larger basis set did not show any improvements.

The ROA spectrum of (+)-3-methylcyclohexanone [7] showed some couplets, which gave rise to much discussion about their origin. Assignments of those vibrations were based on semiempirical calculations with limited reliability. The latest spectrum, however, together with an *ab initio* vibrational analysis, attributes, for example, the couplet at 494 and 518 cm^{-1} to a ring-bending mode and an antisymmetric in-plane C=O bending motion coupled to the bending motion of the methyl

group relative to the ring and correctly assigns the (*R*)-configuration to the molecule.

Using ECD and ROA, a computational and experimental study of 1-(*R*)-phenylethanol (Figure 3) and 1-(*R*)-phenylethylamine and its protonated cation, their hydrated clusters in the gas phase, and their nonpolar and aqueous solutions has been undertaken. Emphasis is placed on the influence of specific, hydrogen-bonded interactions with the aqueous solvent. Further links connecting the structures and conformations of chiral molecules, and their explicitly solvated clusters in the gas phase, to their structures and conformational populations in solution can be expected through measurement, *ab initio* computation, and analysis of their vibrational ROA spectra.

An extensive study focuses on terpenes with structures related to pinane, camphor [8], and limonene [9]. The in-phase dual circular polarization (DCP₁) ROA spectra and the normalized CIDs are presented for 14 compounds. Correlations between ROA features and structural elements of the molecules are discussed. The study clearly demonstrates the advantage of the backscattering measurements, which for theoretical reasons should be about three times as intensive as the normal right angle incident circular polarization (ICP) measurements.

The Raman and ROA spectra of the aqueous solutions of the hydrochloride salts of four medically applied ephedrine molecules have been compared in the $700\text{--}1700\text{ cm}^{-1}$ region. The salts of (1*S*,2*R*)-ephedrine [10], (1*S*,2*R*)-nor-ephedrine [11], (1*S*,2*S*)-pseudoephedrine [12], and (1*S*,2*S*)-norpseudoephedrine [13] show some bands that, with a high

Figure 3 Experimental and computed (B3LYP/6-31 + G* at 532 nm, 15 cm^{-1} Gaussian convolution) Raman and Raman optical activity (ROA) spectra of 1-phenylethanol, neat sample, harmonic frequencies not scaled. The normal modes of a number of weak or 'missing' vibrations computed at the B3LYP/6-31 + G* level are also shown. Reproduced from Macleod NA, Butz P, Simons JP, Grant GH, Bakera CM, and Tranter GE (2005) *Physical Chemistry Chemical Physics* 7: 1432–1440, with permission.

degree of probability, can be used as configurational ROA markers. For example, a band near 840 cm^{-1} , strongly positive for [11]–[13], reflects the chirality at C-1 and probably arises from the symmetric CCO stretch, whereas a band near 910 cm^{-1} , which is strongly negative in [11] and [12], arises from the antisymmetric CCO stretch at C-1. The chirality of the $-\text{C}^*\text{HCH}_3(\text{NH}_2\text{R}^+)$ moiety at C-2 may be reflected by the bands of the antisymmetric methyl deformation at 1450 cm^{-1} , as they are oppositely signed in the two (1*S*,2*R*)-ephedrine (both positive) and the two (1*S*,2*S*)-pseudoephedrine (both negative).

Crystals

Optical activity in crystals not only is a single-molecule effect but also comprises the effects of a large array of similar entities. This is why the crystal ROA is about one order of magnitude larger, and one can measure vibrations that cannot be observed in solutions or neat liquids. But one has to be careful not to observe artifacts produced by the linear birefringence of the crystals. An interesting class of crystals is the cubic crystals of the sodium halogenates.

These are composed of achiral subunits forming a chiral array and therefore crystallize in enantiomorphic crystals, belonging to space group T^4 ($P2_13$). In the ROA spectra of sodium chlorate and bromate, longitudinal and transverse optical F phonons could be resolved. As an example, the depolarized right angle scattering spectra of sodium bromate are shown in **Figure 4**. At a resolution of 1.8 cm^{-1} , the nondegenerate longitudinal (LO) and doubly degenerate transverse (TO) optical modes can be observed separately. The observed signs can be attributed to one of the two possible chiral arrays.

Biochemical Application

One of the great advantages of Raman spectroscopy over IR spectroscopy is the ready applicability of water as a solvent.

This is of course very important in biochemistry, where the compounds to be studied have preferably to be dissolved in water, as that is their natural medium. Nearly all biochemical compounds are chiral, so it is reasonable to study them not only by Raman spectroscopy but also by ROA, where additional features can be observed or resolved.

In this article only small biological molecules are covered; biomacromolecules are covered in another article.

Carbohydrates

The spectra of carbohydrates can be measured with high quality in saturated aqueous solution, exhibiting clear bands that can be readily attributed to the orientation of OH substituents, anomeric preference, and the

Figure 4 Depolarized right-angle scattering Raman and ROA spectra for the lattice vibrations of (+)- NaBrO_4 (solid line) and (-)- NaBrO_4 (dashed line, both 1.8 cm^{-1} resolution). Reproduced from Lindner M, Schrader B, and Hecht L (1995) *Journal of Raman Spectroscopy* 26: 877, with permission.

conformation of exocyclic CH_2OH groups. As 15 monosaccharides (e.g., arabinose, glucose, xylose, galactose, and mannose) were examined, the conclusion that the ROA features reflect local stereochemical details is based on enough material to be reliable.

Conformational changes of glucose, galactose, and lactose on transition from the gas phase to aqueous solution at room temperature have been monitored by vibrational Raman and ROA, complemented by IR ion dip (IRID) spectroscopy conducted at low temperatures, nuclear magnetic resonance (NMR) measurements, and calculations. It has been found that glucose and galactose alter their conformational preferences when going to the singly hydrated complexes in the gas phase, and keep that preference in solution. In contrast, the conformational preference of the isolated $\beta(1 \rightarrow 4)$ -disaccharide lactose, which resists conformational alteration when singly hydrated, changes when it is transferred to aqueous solution at 298 K. The computational evidence suggests the control is exerted by entropic effects associated with a loosening of the structure around the glycosidic linkage.

In di- and polysaccharides, ROA can probe the type and conformation of the glycosidic link. Early investigations on D-maltose [14] showed a glycosidic couplet at $890\text{--}960\text{ cm}^{-1}$ similar to that of D-glucose [15]. It is concluded that for the $\alpha(1 \rightarrow 4)$ -glycosidic link, the couplet is positive at low and negative at high wave numbers.

ROA observed at lower wave numbers is also valuable for the determination of configuration. Compared to D-galactose, the disaccharide D-maltose and the polysaccharide laminarin [16] show a large ROA couplet centered at approximately 430 cm^{-1} . The configuration giving rise to a couplet negative at low and positive at high wave numbers is a β -glycosidic link (e.g., D-cellobiose,

laminarin), whereas an α -glycosidic link (D-maltose) is positive at low and negative at high wave numbers.

An extension of the investigations to the disaccharides D-maltose, D-maltose- $O\text{-d}_8$, D-cellobiose, D-isomaltose, D-gentobiose, D-trehalose, and α -D-cyclodextrin confirms these results.

Amino Acids

ROA spectra of L-(S)- as well as D-(R)-alanine [17], together with a detailed *ab initio* vibrational analysis of their zwitterionic structure at the 6-31G and the 6-31G* level, have been reported. Although in the Raman spectra dependence on pH is clearly visible, the ROA spectra are not influenced by H^+ concentration. From the fact that VCD spectra do respond to pH variation, it is concluded that ROA is more directly coupled to chirality and thus can yield more reliable information about absolute configuration.

The simple amino acids L-serine, L-cysteine, L-valine, L-threonine, and L-isoleucine have been studied in aqueous solution by backscattering, using the spectral range from 600 to 1600 cm^{-1} . Bands originating in $\text{C}_\alpha^*\text{H}$ deformation and the symmetric CO_2 stretch provide the best signatures for stereochemical studies. ROA of the former vibration is positive for all acids studied, and that of the latter is negative. Isoleucine is an exception as it shows a nearly featureless ROA spectrum. The reason may be that it exists as an equal mixture of two rotamers in water.

Ab initio (B3LYP/CPCM/6-31++G**) computations of the Raman and ROA spectra of the conformers of the L-alanine zwitterion revealed that the shapes of the spectral bands are to a large extent determined by the rotation of the NH_3^+ , CO_2^- , and CH_3 groups. For comparison, Raman and ROA spectra of a glassy, crystalline, and dissolved alanine were taken. The spectra of

the aqueous solution of the alanine zwitterion were also compared to the spectra of some flexible rigid dipeptides.

Dipeptides

Simulated ROA spectra (BPW91/COSMO/6-311G**) of the four lowest energy conformations of the zwitterionic dipeptide L-alanyl-L-alanine [18] were compared to solution ROA spectra. As normal *ab initio* calculation simulated the molecule in a vacuum and did not succeed in finding a stable conformer, the implicit COSMO model of solvent was used to calculate realistic geometries.

A series of the Pro-Gly, Gly-Pro, Pro-Ala, and Ala-Pro dipeptides were subjected to conformer analysis using density functional computations and numerical decomposition of the spectral shapes. All observed transitions were assigned, and the computed transition frequencies were scaled accordingly. Then the populations observed by Raman and ROA spectroscopy agreed within a few percent with an analysis of the spin-spin coupling constants based on the Karplus equations, which was also confirmed by a comparison of calculated and experimental NMR couplings.

In an experimental and *ab initio* computational study, the conformation of the dipeptide cyclo(L-Pro-L-Pro) was monitored by its NMR and ROA spectra. The spectra were then simulated by DFT calculations using the BPW91 functional and the 6-311G** basis set.

Nucleosides and Nucleotides

Pyrimidine nucleosides have been studied in back-scattering. Unlike in normal Raman spectroscopy, where the sugar moiety only gives rise to weak signals, ROA detects signals of comparable intensity as well from the sugar, as from the interaction of the sugars with the bases, but no signals from nearly achiral vibrations localized in the planar base rings. Of great diagnostic value are signals arising from the stretching at the C(1')-N(1) glycosidic bond. These signals (~ 1200 , 1230, 1380, and 1400 cm^{-1}) have opposite signs for α - and β -thymidine.

Other Applications

Apart from probing molecular conformation and configuration, ROA has been employed to a couple of other tasks.

The applicability of ROA for the determination of enantiomeric excess in mixtures of chiral enantiomers was exploited. Using the test compound α -pinene an accuracy of 0.1% ee was achieved.

The possibility of observing ROA from chiral surfaces has been mentioned and a theory for the generation of second-harmonic optical activity (SHOA) from chiral surfaces and interfaces has been derived.

Even theoretical aspects may be attacked by ROA spectroscopy. In benzene derivatives containing heteroatoms, the question arises whether Rydberg transitions centered on the heteroatom are involved. Using a comparison between the polarized and depolarized ROA spectra, this contribution of Rydberg transitions could be detected in 1-phenylethanol and 1-phenylethylthiol, as large deviations from the factor of 2 in the ratio of polarized to depolarized spectra were found.

Also, the importance of the electric dipole-electric quadrupole polarizability tensor in the intensity theory of ROA spectra has been examined using DFT and some organic cyclic compounds, alanine, oligoalanines, and so on.

VROA can be surface-enhanced as can the normal Raman effect. This has been verified with adenine in silver colloidal solution. Simulations of the surface-enhanced Raman optical activity (SEROA) using time-dependent density functional theory (TDDFT) have been presented on adenine with silver clusters.

ROA	Raman optical activity
SCP	scattered circular polarization
VCD	vibrational circular dichroism

Raman optical activity (ROA) or, more precisely, spontaneous vibrational ROA scattering is, like vibrational circular dichroism (VCD), a spectroscopic method that directly probes the handedness, or chirality, of molecular vibrations. ROA of molecular origin was the first of the two phenomena to be measured, though not by much, in 1973. The decisive technologies that enabled the experimental demonstration of ROA were the invention of the argon ion laser, the availability of KD*P electrooptic modulators developed for laser Q-switching, and single-photon counting.

Decisive progress on the reliable collection of ROA data has been made since, and commercial spectrometers have made their appearance. Most present instruments use a backscattering configuration first described at the beginning of the 1980s rather than the earlier right angle configuration. Backscattering is expected to remain the preferred arrangement for biological samples, but for analytic purposes, right angle scattering retains the advantage of requiring smaller samples.

The advances in the measurement of ROA over the past three decades fall into three categories. The first reflects the progress in general Raman instrumentation: multichannel detection with backthinned charge-coupled devices (CCDs) combined with high-luminosity spectrographs based on holographic grating technology, and solid state lasers replacing gas lasers. The second is the conceptual solution of the offset problem ubiquitous in optical activity and the scourge of early ROA measurements. The third are improvements in light collection, sample cell, and handling techniques that have led to a reduction in the amount of the sample required by an order of magnitude, to less than a microliter, and also in backscattering.

ROA Variants

There is a wide variety of scattering geometries and polarization schemes that can be used for ROA measurements. Some instrumental parts are common to all, such as lasers, spectrographs, and detectors, but light collection optics and offset reduction schemes may differ. This article will concentrate on the practically relevant or promising arrangements and merely point out others. It will discuss neither the potential use of Fourier transform Raman spectroscopy for ROA nor nonlinear ROA, as no experiments have been demonstrated.

Basic Measurement Arrangements

The scattering geometries of practical importance are right angle (90°), backward (180°), and forward (0°) scattering. The 0° and 180° scattering geometries yield different ROA information, in contrast to ordinary Raman scattering where the signals are identical. ROA intensities are, in general, largest for 180° and smallest for 0° scattering, with 90° somewhere in between, but details depend on the particular Raman band one observes.

For any chosen scattering angle, ROA can be observed either by modulating the incident light between right and left circular (ICP, incident circular polarization) or by analyzing the content of the right and left circular component in the scattered light (SCP, scattered circular polarization). This analysis can be done either by separately measuring the intensity of each circular component or by determining the ellipticity of the scattered light, but only the first method has so far found practical application. The simultaneous modulation of the circularity of the incident light and of the analysis of the

Table 1 Invariant combinations of SCP scattering cross sections for different geometries. ICP cross sections are a factor of 2 larger because they apply to the combined results of a distinct right and left modulation period

Scattering angle	Incident polarization	Difference $\frac{4(K/c)}{4(K/c)}$	Sum $\frac{Sum}{K}$
0°	Unpolarized	$90\alpha G' + 2\beta_G^2 - 2\beta_A^2$	$90\alpha^2 + 14\beta^2$
180°	Unpolarized	$12\beta_G^2 + 4\beta_A^2$	$90\alpha^2 + 14\beta^2$
90°	Polarized	$45\alpha G' + 7\beta_G^2 + \beta_A^2$	$90\alpha^2 + 14\beta^2$
	Depolarized	$6\beta_G^2 - 2\beta_A^2$	$12\beta^2$
Integral	Unpolarized	$\frac{2\pi}{3}(180\alpha G' + 40\beta_G^2)$	$\frac{4\pi}{3}(180\alpha^2 + 40\beta^2)$

$\alpha G'$, isotropic ROA invariant due to the optical activity tensor; β^2 , anisotropic Raman invariant; c , speed of light.

circular polarization of the scattered light yields two dual circular polarization schemes, namely, DCP_I for in-phase and DCP_{II} for out-of-phase modulation and detection, where in-phase means the detection of the right circular content when the incident light is also right circularly polarized. The information provided by the two schemes differs and DPI_I only is of stereochemical interest.

In an ICP experiment, the scattered light may or may not be polarization analyzed with a linear polarizer, and in an SCP experiment the exciting light can be linearly or naturally (n) polarized. In right angle scattering this allows the determination of a polarized and a depolarized ROA component, depending on whether the orientation of a linear polarizer is chosen perpendicular or parallel to the scattering plane, respectively.

Of the multitude of experimental configurations ensuing from the combination of different geometries and polarization schemes, those of practical relevance are collected in **Table 1**. Included is the theoretically important cross section for scattering into a solid angle of 4π as its combination of tensor invariants is devoid of quadrupole contributions, and as it can readily be obtained from a polarized and a depolarized right angle ROA measurement.

The Comparison of Experimental Data

Except for band positions, measurements that yield different combinations of invariants of the scattering tensors according to **Table 1** are not comparable. The ratio of the five Raman and ROA invariants of the scattering tensor can be extracted from three separate measurements, but this has been done only once. A qualitative comparison of backscattering with depolarized right angle ROA spectra can be meaningful if both are determined by the anisotropic invariant β_G^2 . The quantitative comparison of ROA data with the same invariant combination is possible, in the form of recorded photons per joule of exciting energy, if the data have been recorded under identical conditions. Absolute scattering cross sections have so far not been measured in ROA.

A better than merely qualitative comparison of ROA spectra measured under different conditions can be based

on the dimensionless ratio Δ of ROA to Raman scattering, which is independent of many instrumental parameters. For SCP backscattering (scattering angle $\theta = \pi$) with naturally (n) polarized exciting light one has for the average value, and the difference, respectively, of the differential scattering cross sections ${}^n d\sigma_{pL}$ and ${}^n d\sigma_{pR}$, for vibration p for left (L) and right (R) circularly polarized light

$${}^n d\sigma_p(\pi)_{\text{SCP}} = \frac{1}{2}({}^n d\sigma_{pR} + {}^n d\sigma_{pL})$$

$$= K_p(90\alpha_p^2 + 14\beta_p^2) d\Omega \quad [1]$$

$$-\Delta {}^n d\sigma_p(\pi)_{\text{SCP}} = -({}^n d\sigma_{pL} - {}^n d\sigma_{pR})$$

$$= \frac{4K_p}{c}(12\beta_{Gp}^2 + 4\beta_{Ap}^2) d\Omega \quad [2]$$

$$K_p = \frac{1}{90} \left(\frac{\mu_0}{4\pi} \right)^2 \omega_0 \omega_p^3 \quad [3]$$

The minus sign for $\Delta d\sigma$ renders the standard definition of molecular quantities as left minus right in optical activity compatible with the ROA convention to represent scattering intensities as right minus left. ω_0 and ω_p are the pulsations of the exciting and the scattered light, respectively, c the speed of light, and μ_0 is the permeability of the vacuum. Δ values follow from eqns [1] and [2] as

$$\Delta_p(\pi)_{\text{SCP}} = \frac{{}^n dI_{pR}(\pi) - {}^n dI_{pL}(\pi)}{{}^n dI_{pR}(\pi) + {}^n dI_{pL}(\pi)}$$

$$= \frac{{}^n d\sigma_{pR}(\pi) - {}^n d\sigma_{pL}(\pi)}{{}^n d\sigma_{pR}(\pi) + {}^n d\sigma_{pL}(\pi)}$$

$$= \frac{2}{c} \frac{12\beta_{Gp}^2 + 4\beta_{Ap}^2}{90\alpha_p^2 + 14\beta_p^2} \quad [4]$$

where ${}^n dI_{pR}$ and ${}^n dI_{pL}$ are the scattering intensities for right and left circularly polarized light, respectively, for scattering into an infinitesimal element of the solid angle Ω . $d\sigma$ measures the rate at which energy is removed from the incident beam by scattering, relative to the rate at which energy crosses a unit area perpendicular to the direction of propagation of the incident beam. $d\sigma/d\Omega$ relates to the power scattered into a given element of

solid angle $d\Omega$, and dI is therefore proportional to it. Expressions for other scattering geometries follow from the invariant combinations in Table 1.

In an actual measurement, a substantial solid angle is used for collecting light, and measured Δ values depend on this light collection angle. They depend further on the resolution of the instrument because isotropic and anisotropic invariants of the scattering tensor lead to bands of different width. Δ also depends on the exciting wavelength λ as $1/\lambda$. This dependence is not explicit in eqn [4] but follows from the frequency dependence of the invariants.

A second way to compare two experimental ROA spectra a and b can be based on their similarity S_{ab} defined as:

$$S_{ab} = \frac{\sum_{\tilde{\nu}=\tilde{\nu}_1}^{\tilde{\nu}_2} I_{a,\tilde{\nu}} I_{b,\tilde{\nu}}}{\sqrt{\sum_{\tilde{\nu}=\tilde{\nu}_1}^{\tilde{\nu}_2} I_{a,\tilde{\nu}} I_{a,\tilde{\nu}}} \sqrt{\sum_{\tilde{\nu}=\tilde{\nu}_1}^{\tilde{\nu}_2} I_{b,\tilde{\nu}} I_{b,\tilde{\nu}}}} \quad [5]$$

The summation is over discrete wavenumbers $\tilde{\nu}$ between the limits $\tilde{\nu}_1$ and $\tilde{\nu}_2$. The similarity of spectra with the same intensity ratio of bands has a value of 1. Spectra recorded in a flat window sample cell and a capillary yielding lower scattering intensities will retain this value, except for the influence of a different light collection angle.

S_{ab} and Δ are useful for identifying instrumental artifacts.

Noise and Its Reduction in ROA Measurements

ROA is a small difference of two already small quantities, with values of $|\Delta|$ rarely exceeding 10^{-3} . Noise therefore sets the limits to the measurement of ROA.

There are three noise components that can be distinguished: shot noise, flicker noise, and deterministic offset. They affect spectra differently, and their reduction requires distinct approaches.

Shot Noise

In the shot noise limited case, where the Raman intensity I is represented by N events, in our case detected scattered photons, the statistics of a Poisson distribution hold. With $I_R \approx I_L \approx I$, the rms deviation of $\overline{\Delta N}$ corresponding to $\Delta I = I_R - I_L$ is $\sqrt{2N}$. Thus, to recover $\overline{\Delta N} = |\Delta| \times \overline{N}$ with a signal-to-noise ratio of η , the number of detected photons needs to be

$$\overline{\Delta N} = |\Delta| \times \overline{N} = \eta \sqrt{2N}, \quad \overline{N} = 2 \frac{\eta^2}{\Delta^2} \quad [6]$$

For a typical value of $|\Delta| = 5 \times 10^{-4}$ and a desired minimal rms signal-to-noise ratio of $\eta = 10$, one needs to detect close to 10^9 photons per spectral element of

resolution. This number is put into perspective by comparing it to the value of 5.5×10^4 detected photons per second obtained in backscattering at 4 cm^{-1} resolution with a modern commercial Raman instrument, equipped with a CCD detector and a 15 mW He-Ne laser, for the peak height of the exceptionally strong 992 cm^{-1} band of benzene.

In comparison to shot noise, in view of the large number of photons needed in ROA, readout noise is negligible for modern slow-scan CCD detectors.

The recipes for the reduction in shot noise are simple: an exciting laser with sufficient power, efficient collection of the scattered light, spectrographs with a large étendue (the amount of light that an optical system is capable of collecting), and multichannel detectors with a high quantum efficiency. Shot noise reduction has reached limits that cannot easily be pushed much further.

It is the one area where ROA has profited most from the general advances in Raman instrumentation.

Flicker Noise

While shot noise, which follows a Gaussian distribution, increases as the square root of the measurement time, with the signal-to-noise ratio improving at the same rate, the cumulative error due to flicker noise tends to increase faster than shot noise. The improvement in the flicker signal-to-noise ratio with measurement time can therefore be slow or nonexistent. In clocks, for example, after the elimination of all systematic drifts, there remains an error due to flicker noise that is known to increase at least linearly with time. No analysis of flicker noise sources in ROA has been published. The influence of dust in the sample, which tends to get trapped by the optical tweezer effect in the waist of the focused laser beam, is well known, as is the influence of optical schlieren through local heating. Flicker noise in ROA does not seem to follow the $1/f$ behavior often observed for electronic circuitry, with f being the frequency, but it is prominent at low frequencies. Reducing it requires high modulation rates in ICP, or a switch to SCP where it can be reduced by the simultaneous detection of right and left circularly polarized scattered light.

Deterministic Offset

Spurious signals due to systematic instrumental offset are akin to deterministic drift in a clockwork. Such artifacts neither are reduced by an increase in observation time, nor they can be detected by the comparison of subsequent measurements done with the same instrument under identical conditions. Deterministic offset is at the root of early erroneous reports of measured vibrational optical activity.

The mechanisms leading to spurious signals can have their root in timing errors, electrical and mechanical

perturbations synchronized with the data acquisition cycle, or optical errors leading to unequal intensities for right and left circular light unrelated to the sample's ROA properties. The sample itself might exhibit undesirable characteristics such as turbidity, an optically active fluorescent background, or differential absorption for right and left circularly polarized light.

From the point of view of optical offset, depolarized right angle ICP is the easiest ROA measurement as imperfections in the circular polarization of the exciting light do not produce artificial scattering differences. This is true for small light collection angles. The reliable recording with large collection angles requires optics such as the dual-lens light collection system used for the first recording of polarized right angle ICP ROA. The successful measurement of ICP backscattering depends, in turn, on the depolarization of the scattered light because dispersive systems and detectors are polarization sensitive.

SCP backscattering is highly sensitive to a component of circularly polarized light in the exciting light, as it will show up, depending on the polarization of Raman bands, as a spurious ROA signal. With linearly polarized exciting light, optical birefringences in the focusing lens and the scattering cell, even with otherwise perfect optics, tend to render the light in the scattering zone elliptical. Routine SCP measurements therefore require depolarized exciting light. An often overlooked problem are reflections of the exciting and the scattered light on optical surfaces, including the walls of the scattering cell.

Instrument Building Blocks

Figure 1 gives an overview of the major functional parts of a backscattering SCP ROA spectrometer. In an ICP instrument, a circular polarization modulator in the incident light would replace the circular polarization analyzer in the scattered light. A DCP instrument would be obtained by combining the SCP and ICP building blocks. A dual-arm system is not mandatory for ICP and DCP, but switching the scattered light between two arms, synchronized with a rapid modulation of the exciting light, is a way to reduce flicker noise.

Lasers

Except for sufficient power, no particular requirements exist for the exciting laser. The tiny ROA effects of chirally deuterated neopentane were measured in backscattering with a frequency-doubled Yb:YAG thin-disk laser intended for display and machining purposes. Such lasers have no longitudinal coherence and are not transverse single mode. A laser's transverse mode properties can matter in right angle scattering where the waist of the focused beam is imaged onto the entrance slit of the spectrograph.

The choice of exciting wavelengths in ROA has followed the availability of sufficiently reliable and powerful lasers: the 488 and 514.5 nm lines of the argon ion laser were initially used, but now the 532 nm line of the frequency-doubled YAG is common. Excitation in the red or near-infrared region would be preferable for reducing Raman spectroscopy's ubiquitous fluorescence problem. The $1/\lambda$ dependence of Δ , in addition to the fourth power $1/\lambda$ dependence of Raman scattering, and the lack of sufficiently powerful and reliable continuous wave lasers in the 650–800 nm range, have hampered ROA at these longer wavelengths. CW laser powers of tens of watts are easily available at 1.06 μm , the wavelength of the nondoubled YAG, but problems with sample heating by the absorption of vibrational overtones, and the lack of suitable multichannel detectors, render 1.06 μm excitation unattractive.

With green exciting light, 100–400 mW of laser power at the sample is typical for measurements of organic liquids, but 1000 mW can be desirable for aqueous solutions of proteins.

Focusing and Light Collection Optics

Figure 2 shows the focusing and light collection optics of an SCP instrument capable of measuring forward and backward scattering. A single Gradium lens is often used for focusing and collecting the backscattered light, but separate lenses as depicted in the figure allow for a softer focusing of the laser in the sample, and they eliminate stray light from fluorescence and Raman scattering produced inside a focusing lens also used for light collection.

The nonimaging optics collect the light from a 2–3 mm long segment of the focused beam in the sample, as discussed in the context of sample cells ('see Sample Cells'). This length is determined by the focal length of 30 mm of the light collection lens, 100 mm of the lens focusing light onto the fiber optics, and the diameter of approximately 1.56 mm of each of the two circular entrance ends of the fiber optics cross section transformer. Its two branches guide the light due to the right and left circular component of the scattered light into the spectrograph, as shown in **Figure 1**.

Figure 3 shows a light collection optics capable of filling, also in right angle scattering, the étendue of a modern holographic planar grating spectrograph. In ICP, the dual-lens system also suppresses offsets otherwise caused by a deviation from circular of the polarization of the exciting light. Throughput can exceed that achievable with fiber optics in backscattering.

Polarization Conditioning and Polarization Analyzing Optics

Precise polarization control is quintessential to the elimination of offset in all but depolarized ICP right

Figure 1 Building blocks of an SCP ROA backscattering spectrometer.

angle scattering. The decisive advance that makes the recording of ROA routine and advantageous for other arrangements is the optical creation of a virtual enantiomer, combined with scrambling of linearly polarized components in the exciting and the scattered light. **Figure 4** shows the optical arrangement used in a modern SCP backscattering instrument. A detailed analysis requires the Stokes–Müller formalism, but the principle can be understood without it.

There are two related properties of half-wave plates that are exploited. The first is the interconversion of right

and left circular light passing through them, and the second is the rotation of the plane of polarization of linear incident light by twice the angle it makes with a wave plate's fast optical axis. As a consequence, all chiroptical properties of a molecule, as observed from the outside, correspond to those of its enantiomer if the molecule is placed between half-wave plates with aligned axes. The circularity converters CC_1 and CC_2 in **Figure 4**, which are moved into and out of the exciting and scattered light, respectively, serve the purpose of forming a half-wave cage about the sample. Two measurements are made, one

Figure 2 Focusing and light collection optics for backward and forward scattering. L_1 : 100 mm focusing lens; L_2 and L_3 : 30 mm $f/1.1$ Gradium light collection lenses; M_1 , M_2 , and M_3 : beam deviation mirrors; BD: beam dump; S: sample. The actual orientation of M_1 and M_2 is at 90° to each other so that their polarizing properties cancel.

Figure 3 Offset compensating dual-lens light collection optics for right angle scattering with less than $0.5 \mu\text{L}$ samples. L_1 and L_2 form the intermediate image I_1 , which is projected by L_4 onto the spectrograph entrance slit S. L_3 is a field lens.

Figure 4 Offset elimination optics for collinear scattering. LR_1 , LR_2 , and LR_3 : rotating half-wave plates; CC_1 and CC_2 : half-wave plates moved into the optical train for creating a virtual enantiomer. The mirrors M_1 and M_2 provide polarization neutral beam deflection.

without and one with the half-wave plates in place. The second measurement is treated as if it had been performed for a real enantiomer. Subtracting it from the first one yields twice the value of a single measurement. The sequence of four measurements used in practice is more complicated but based on this idea.

Offsets other than those that depend on the chiroptical properties of the sample, and on imperfections of the optics between the circularity converters CC_1 and CC_2 , are eliminated. The linear rotators LR_1 and LR_2 linearly depolarize the exciting light, and LR_3 the scattered light. This cancels the effect optical rotation and stray birefringences may have, and it obviates the need to orient the axes of CC_1 and CC_2 . Counter-rotating half-wave plates in the incident light increases the speed of rotation of the plane of polarization to over 50 000 rpm, and their relative rate of rotation of 29:33 reduces the influence of their imperfections.

Spectrographs and Detectors

Spectrographs with planar holographic transmission gratings have become the norm in ROA spectroscopy. The high-speed entrance optics of commercial spectrographs is ill-suited for coupling with the fiber optics of the dual-arm SCP backscattering arrangement of **Figure 1**. The 2×31 fibers with a $215 \mu\text{m}$ core and a $245 \mu\text{m}$ overall diameter have a low f -ratio degradation and accept light in an approximately $f/2.2$ cone. The length of the curved output surface of the cross section transformer, which directly substitutes for the entrance slit of the spectrograph, amounts to 15.5 mm and requires large diameter optics in order to avoid vignetting. The speed of the light coupled into the fiber optics is $f/3.65$. Aberration correction can thus be modest, and a single achromatic lens with 76 mm diameter and 200 mm focal length suffices as entrance optics. The modified spectrograph, based on a Kaiser Optical Systems HoloSpec, is shown in **Figure 5**.

Efficiencies of holographic transmission gratings for s and p polarization (perpendicular and parallel to the plane of incidence of the grating) is claimed to be close to

Figure 5 Holographic plane transmission grating spectrograph with an étendue of $1.6 \text{ mm}^2 \text{ sr}$ (steradian) and an $f/3.3$ entrance speed for fiber optics coupling. S: curved entrance slit formed by fiber optics on a 217 mm diameter circle, length 15.5 mm, average optical width 0.169 mm ; curvature is determined by $\phi = 40^\circ$ and $\theta = 50^\circ$ and is the same with 532 nm excitation for a 0–2400 and a 1555–3825 cm^{-1} grating G; L_1 : achromat, $f = 200 \text{ mm}$, $\varnothing = 75 \text{ mm}$; L_2 : photographic lens, $f = 85 \text{ mm}$, $f/1.4$; FP: focal plane with $6.6 \times 27 \text{ mm}^2$ (256×1024 pixel) backthinned CCD detector. Average optical resolution is 7 cm^{-1} , and one column of the detector covers a spectral interval of approximately 2.4 cm^{-1} .

100 and 60%, respectively. Owing to right angle bends in perpendicular planes, the output light of the fiber optics is partially depolarized, and the efficiency for light coming from the s and p arm of the polarization analyzer is similar. The two halves of the fiber optics are each imaged onto a 128-pixel-wide strip of a backthinned CCD with 256×1024 pixels. The curvature of the slitlike part of the fiber optics corresponds to a circle with a 217 mm diameter fitted to the central segment of a parabola. It leads to a straight line image on the detector so that binning can be used when the CCD is read.

Data Acquisition Logic

A basic acquisition cycle of a circular intensity difference measurement consists in measuring and subtracting the Raman intensity for right and left circular polarization. Synchronization is required for the illumination of the sample, for reading the detector while illumination is switched off, and in ICP for switching the circular polarization of the exciting light. The basic cycle is complicated by the need to synchronize the motion of the optical elements that create the virtual enantiomer and that scramble components of linear polarization. The timing diagram of **Figure 6** summarizes important aspects for the SCP instrument of **Figure 1**.

The two arms of the instrument each measure the intensity of either the right or the left circular component of the scattered light, depending on the switching state of the liquid crystal quarter-wave retarder of the circular polarization analyzer. The sum for two switching states, a dual acquisition cycle, has a vastly increased precision as differences in the arms' transmissions are eliminated.

The polarization scramblers LR_1 and LR_2 rotate the plane of polarization of the exciting light by an integral number of turns during an illumination window. A trick

Figure 6 SCP acquisition cycle for a single fixed position of the circularity converters CC_1 and CC_2 . The CCD detector is read, and the liquid crystal retarder (LCR) is switched, when illumination of the sample is off. The circularity converters are moved to the next of four relative positions during the last dark interval.

to reduce the required high timing precision is to consider not individual dual acquisition cycles but rather blocks of four of them, and to start consecutive dual cycles with the plane rotated by 45° , by slightly extending every second dark period. Synchronization of the polarization scrambler LR_3 in the scattered light is not needed for long acquisition times, but it is important for short acquisitions, such as the recording of the spectra of the anomers of glucose discussed in the section entitled 'Experiment ROA Data'.

The two half-wave plates used to create the virtual enantiomer are moved into and out of the optical train after four dual acquisition cycles. It is more effective to move them individually instead of together, resulting in four different relative positions. The shortest complete ROA data acquisition cycle then comprises $4 \times 4 \times 2$ individual illuminations of the sample.

Sample Cells

The amount of substance required is a decisive characteristic of any analytical method. Early right angle

Figure 7 Quartz (35 μl) and black Teflon (22 μl) cylindrical sample cells. The inlets are shaped to fit standard 100 μl polypropylene pipette tips. O-joints are made from Kalrez. (DuPont Performance Elastomers L.L.C.).

Figure 8 Light collection zone of the nonimaging optics for a sample with an index of refraction $n_2 = 1.47$ (fused quartz) and a cell with flat windows. The curved surface of capillaries increases the internal light collection angle and shortens the zone of light collection.

measurements with micro-capillaries proved that ROA can be determined with less than 1 μl of sample, but sample volumes of more than 100 μl were standard. Rectangular cells requiring 100 μl are still common today in backscattering, even though cylindrical cells with less than a quarter of this volume yield data of the same quality. **Figure 7** shows a cylindrical quartz cell for backscattering with a volume of 35 μl and a cell fabricated from black Teflon with a pathlength of only 3 mm and a volume of 22 μl . Small microscope cover glasses are used as its windows. Their thickness of only 0.15 mm reduces collection of Raman light from glass, and they can be replaced should material get burned to their surface.

The shape of the zone from which light can be collected by the optics matters for the design of sample cells. The nonimaging optics in **Figures 1** and **2** collect light

from a volume situated within a double-sided cone as shown in **Figure 8**. For a central diamond-shaped zone, light with a solid angle filling the $f/1.1$ Gradium lens is collected, with efficiency falling off outside this boundary. This makes for efficient light collection from the 50–100 μm diameter waist of a multimode laser beam focused by a 100 mm lens at the center of the light collection zone.

The curved surface of a capillary shortens the light collection volume, similar to a reduction in the value of n_2 , for light scattered in a plane perpendicular to the capillary's axis. This explains why the loss of Raman intensity amounts to 40% only for capillaries with an inner diameter (ID) of 1.4 mm, as compared to larger flat window cells. The loss increases for 0.56 mm ID capillaries required for sample volumes of 1 μl or less. For organic liquids, the collection of Raman scattered light

from a capillary's thin glass envelope (≤ 0.15 mm) is negligible. It is comparable to that of water when measured in a 1.4 mm ID capillary.

For all types of cells, it is of utmost importance to avoid the collection of Raman light reflected under oblique angles from walls. For capillaries, experience indicates that the scattering zone needs to be situated at a distance of about twice the capillary's ID from either end of the column formed by the sample. For cylindrical cells that are longer than wide, the focus of the light collection optics needs to be placed deep enough into the sample.

Experimental ROA Data

α and β Anomers of Glucose

Depending on the conditions under which it is crystallized, solid D-glucose consists of the α -pyranose or the β -pyranose form of the molecule. On dissolution in water, the initial value of the specific angle of rotation is 112.2° for the α form and 18.7° for the β form. The two anomers interconvert in solution, and the measured

angles converge to a common value of 52.7° over a duration of approximately 3 h.

Until about a decade ago, ROA measurements took far too long for determining the spectra of individual anomers, but recent instrumentation has changed this. **Figure 9** displays spectra of the α and β forms of glucose, each measured with a total exposure time of 600 s with an SCP instrument based on the schematic of **Figure 1**. Recording was done in four slices completed within 5 min of the start of the preparation of fresh solutions by the vigorous shaking of powdered α - and β -glucose for 60 and 30 s, respectively, in distilled water. Each slice comprises only two of the acquisition cycles of 32 exposures discussed in the section 'Data acquisition logic.'

Also shown are the spectra of the same solutions after their equilibration for 3 h. The Raman and ROA intensities, expressed in detected electrons per joule of exciting energy, are larger for the solutions prepared from the β form, indicating a higher concentration despite a shorter mixing time. The similarity S_{ab} , eqn [5], of the spectra reaches 1.0 for Raman and 0.9 for ROA, deviating from 1 due to noise.

Figure 9 Backscattering spectra of the two anomers of D-glucose measured in a cylindrical sample cell. Measurement time: 4×150 s with slices completed within 5 min of the start of the preparation of solutions (see the section on ' α and β Anomers of Glucose'); laser power at sample: 940 mW for the α and 730 mW for the β anomer; exciting wavelength: 532 nm; resolution: 7 cm^{-1} . The curves are slightly smoothed with a third-order Savitzky–Golay procedure and represent detected photons per CCD column with one column covering approximately 2.4 cm^{-1} .

Figure 10 Forward scattering spectra of (–) β -pinene measured in a 1.4 mm ID capillary. Bottom curve: Raman; middle curve: ROA; top curve: degree of circularity inverted to correspond to backscattering convention. Sample size: 8.5 μ l; exposure time: 20 min; laser power at sample: 250 mW; other parameters as in **Figure 9**.

Forward Scattering Measured in Capillaries

ROA forward scattering has been considered difficult as it is generally smaller than backscattering. **Figure 10** shows that it can readily be measured for small quantities in capillaries. Except for the higher precision, this recent spectrum of β -pinene agrees with earlier measurements.

Symbols

$\tilde{a}_{\alpha\beta}$	general scattering tensor
D_1 – D_5	constants
$\tilde{e}_x^i$	polarization vector for incident light
$\tilde{e}_x^s$	polarization vector for scattered light
$\tilde{E}^{(0)}$	electric field strength of incident radiation
g_{eg}	anisotropy ratio
$\hbar$	Planck's constant/ 2π
I	intensity of light scattering
K	a constant
n	initial electronic state
$\tilde{n}_x^i, \tilde{n}_x^d$	propagation vectors for incident and scattered light, respectively
m	final electronic state
$(\vec{m})_{eg}^v$	magnetic dipole transition moment
R	distance from the scattering to the detector
$R_{i,\alpha}$	location of the i th polarizability relative to the origin
α^2	the isotropic invariant
$\tilde{\alpha}_{\alpha\beta}$	Raman polarizability tensor
$\beta_a(\alpha)^2$	antisymmetric anisotropy
$\beta_s(\alpha)^2$	symmetric anisotropy
$\tilde{e}_{\alpha\beta\gamma}$	the unit antisymmetric tensor
ξ	scattering angle
μ_0	magnetic permeability
$(\vec{\mu})_{eg}^v$	electric dipole transition moment
ω	angular frequency

Raman optical activity (ROA) is defined as the difference in Raman scattering intensity for right minus left circularly polarized light. Along with optical rotational and circular dichroism, ROA is a form of natural optical activity. All forms of optical activity can be defined as the differential interaction of a molecule with right versus left circularly polarized radiation. Only chiral molecules exhibit natural optical activity and, for such molecules, the mirror image of the molecule cannot be superimposed on itself. The most common form of ROA is vibrational ROA. Vibrational ROA is also one of two forms of vibrational optical activity. The other form is vibrational circular dichroism (VCD), which is the difference in the IR

absorption of a molecule for left versus right circularly polarized radiation for a vibrational transition. VCD and ROA are complementary, non-redundant forms of vibrational optical activity in the same way that IR absorption and Raman scattering are complementary forms of ordinary vibrational spectroscopy.

There are many forms of ROA, depending on the choice of polarization modulation, scattering geometry and proximity of the exciting laser radiation to resonance with excited electronic states in the molecules. A general theory of ROA can be written from which all special cases can be derived. The first division of the theory is between circular polarization (CP) ROA and linear polarization (LP) ROA. To date only different forms of CP ROA have been measured experimentally. There are four forms of both CP and LP ROA. For CP ROA, the original and most common form is called incident circular polarization (ICP) ROA in which only the state of the incident laser radiation is modulated between right and left circular polarization (RCP and LCP). Analogously, the other three forms are called scattered circular polarization (SCP) ROA, where only the polarization of the Raman scattered radiation is sampled for RCP and LCP content, dual circular polarization one (DCP_I), where both the incident and scattered polarization states are modulated in-phase, and dual circular polarization two (DCP_{II}), where both states are modulated out-of-phase. Similar definitions have been provided for the four forms of LP ROA.

The two principal resonance limits of the theory of ROA are the far-from-resonance (FFR) limit, the original form of the theory of ROA, and the single-electronic-state (SES) limit, for the case of strong resonance between a single excited electronic state and the incident laser radiation. In the case of FFR ROA, *ab initio* calculations have been carried out for direct comparison with experiment. The SES theory is so simple that the complete SES-ROA spectrum can be predicted from the parent resonance Raman spectrum and the electronic circular dichroism spectrum of the resonant electronic state.

ROA is a relatively new spectroscopic tool that has been applied with a high degree of success to the study of the structure of chiral molecules in solution. Areas of application include proteins, nucleic acids, carbohydrates, natural products, pharmaceuticals and other kinds of molecules of biological or therapeutic significance.

Polarized Light Scattering

One of the essential properties associated with the scattering of light by molecules is the polarization state of the light. Changes in the polarization state affect the nature and information content of the scattered light. This holds for Rayleigh scattering, where the frequency of the scattered radiation is unchanged from the exciting laser radiation, and for Raman scattering, where the scattered radiation differs from the incident laser radiation by a vibrational energy change in the molecule. The intensity of light scattering for any experiment can be expressed in terms of the general scattering tensor $\tilde{a}_{\alpha\beta}$ and the polarization vectors for the incident and scattered radiation $\tilde{e}_\alpha^i$ and $\tilde{e}_\alpha^d$, respectively, and is given by

$$I(\tilde{e}^d, \tilde{e}^i) = 90K \left\langle \left| \tilde{e}_\alpha^d \tilde{a}_{\alpha\beta} \tilde{e}_\beta^i \right|^2 \right\rangle \quad [1]$$

In this equation, K is a constant, given below, that depends, among other things, on the intensity of the incident laser radiation. The angular brackets designate an average over all angles of orientation of the molecule to the laboratory frame of reference. This is needed for liquid, solution or gaseous samples where there is no unique molecular axes relative to the laboratory axes. The polarization vectors have one Greek subscript and the scattering tensor has two. For repeated Greek subscripts, summation over the Cartesian directions x, y and z is implied. Hence, eqn [1] has nine terms within the vertical brackets, and these brackets designate the absolute value of the complex quantities within the brackets. The tilde above a quantity, such as a polarization vector or a scattering tensor, indicates that this quantity can be complex. The star superscript for the polarization vector of the scattered light designates complex conjugation. The constant K is given by

$$K = \frac{1}{90} \left(\frac{\omega^2 \mu_0 \tilde{E}^{(0)}}{4\pi R} \right)^2 \quad [2]$$

where ω is the angular frequency of the scattered light, μ_0 is the magnetic permeability, $\tilde{E}^{(0)}$ is the electric field strength of the incident laser radiation, and R is the distance from the scattering to the detector. The general scattering tensor is given through its lowest-order tensors as

$$\begin{aligned} \tilde{a}_{\alpha\beta} = & \tilde{a}_{\alpha\beta} + \frac{1}{c} \left[\varepsilon_{\gamma\delta\beta} \dot{n}_\delta^i \tilde{G}_{\alpha\gamma} + \varepsilon_{\gamma\delta\alpha} \dot{n}_\delta^d \tilde{G}_{\gamma\beta} \right. \\ & \left. + \frac{1}{3} \omega (\dot{n}_\gamma^i \tilde{A}_{\alpha,\gamma\beta} - \dot{n}_\gamma^d \tilde{A}_{\beta,\gamma\alpha}) \right] \quad [3] \end{aligned}$$

where the first tensor is simply the polarizability tensor that is responsible for ordinary Raman (and Rayleigh)

scattering. The four tensors in square brackets are the ROA tensors. The first two are magnetic dipole–electric dipole ROA tensors and the second two are electric quadrupole–electric dipole ROA tensors. The vectors $\dot{n}_\alpha^i$ and $\dot{n}_\alpha^d$ are the propagation vectors for the incident and scattered light, respectively, and $\varepsilon_{\alpha\beta\gamma}$ is the unit anti-symmetric tensor that is +1 for even permutations of the order x, y, z , −1 for odd permutation of this order, and zero if any two directions are the same.

The Raman polarizability tensor is given by

$$\tilde{a}_{\alpha\beta} = \frac{1}{\hbar} \sum_{j \neq m, n} \left[\frac{\langle m | \hat{\mu}_\alpha | j \rangle \langle j | \hat{\mu}_\beta | n \rangle}{\omega_{jm} - \omega_0 + i\Gamma_j} + \frac{\langle m | \hat{\mu}_\beta | j \rangle \langle j | \hat{\mu}_\alpha | n \rangle}{\omega_{jm} - \omega_0 + i\Gamma_j} \right] \quad [4]$$

where $\hbar$ is Planck's constant divided by 2π , and the summation is over all excited electronic states, j , except the initial and final states, n and m , respectively. The states n and m differ by a vibrational quantum of energy. The denominators contain frequency terms, and ω_{jm} is the angular frequency difference between the states j and n . The terms $i\Gamma_j$ are imaginary terms proportional to the width of the electronic state j , and hence inversely proportional to its lifetime. The first term in eqn [4] is called the resonance term since the frequency difference between the jm -transition frequency and the laser frequency vanishes at the resonance condition. The quantities in angular brackets are quantum mechanical matrix elements with electric dipole moment operators μ_α given by

$$\hat{\mu}_\alpha = \sum_k e_k r_{k\alpha} \quad [5]$$

which is simply the summation over the charge and position in the α direction of all particles k , in the molecule, electrons and nuclei.

The matrix element in eqn [4] involving the operator $\hat{\mu}_\beta$ describes the interaction of the molecule with the incident radiation while the matrix elements with the operator $\hat{\mu}_\alpha$ describes the interaction of the molecule with the scattered radiation. The matrix element products in each term can be read from right to left in a time-ordered sense, and hence the resonance term describes the molecule interacting first with a laser photon and subsequently creating a scattered photon, whereas the non-resonance terms reverse the natural order of those two events.

The four ROA tensors differ from the Raman polarizability tensor by substitution of a higher-order operator for an electric dipole operator in eqn [4]. The two operators needed for ROA are the magnetic dipole moment operator and the electric quadrupole moment operator given respectively by

$$\hat{m}_\alpha = \frac{1}{2} \sum_k \frac{e_k}{m_k} \varepsilon_{\alpha\beta\gamma} r_{k\beta} p_{k\gamma} \quad [6]$$

$$\hat{\Theta}_{\alpha\beta} = \frac{1}{2} \sum_k e_k (3r_{k\alpha}r_{k\beta} - r_k^2\delta_{\alpha\beta}) \quad [7]$$

The relationships between the operator substitutions and the resulting ROA tensors in eqn [4] are given by

$$\tilde{\alpha}_{\alpha\beta} \rightarrow \tilde{G}_{\alpha\beta} \quad \text{when} \quad \hat{\mu}_\beta \rightarrow \hat{m}_\beta \quad [8]$$

$$\tilde{\alpha}_{\alpha\beta} \rightarrow \tilde{G}_{\alpha\beta} \quad \text{when} \quad \hat{\mu}_\alpha \rightarrow \hat{m}_\alpha \quad [9]$$

$$\tilde{\alpha}_{\alpha\beta} \rightarrow \tilde{A}_{\alpha,\beta\gamma} \quad \text{when} \quad \hat{\mu}_\beta \rightarrow \hat{\Theta}_{\beta\gamma} \quad [10]$$

$$\tilde{\alpha}_{\alpha\beta} \rightarrow \tilde{A}_{\gamma,\alpha\beta} \quad \text{when} \quad \hat{\mu}_\alpha \rightarrow \hat{\Theta}_{\alpha\beta}, \hat{\mu}_\beta \rightarrow \hat{\mu}_\gamma \quad [11]$$

The expressions given above provide the theoretical formalism for the description of all forms of polarized Raman scattering that are first-order in the magnetic dipole and electric quadrupole interaction of light with matter. This is sufficient to describe the various forms of ROA within the assumptions given above.

ROA Observables

By specifying the desired polarization state of the incident laser radiation and the scattered radiation, it is possible to construct theoretical expressions to describe the various ROA observables that can be measured in the laboratory. If we restrict our attention to circular polarization ROA experiments, the expressions can be obtained from pairs of intensity expressions that differ only in the change in the circular polarization state of one or both the light beams from right circular to left circular, or vice versa.

The fundamental ROA observables are classified by polarization and scattering angle, ξ . There are four different forms of CP ROA given by

$$\text{ICP ROA: } \Delta I_\alpha(\xi) = I_\alpha^R(\xi) - I_\alpha^L(\xi) \quad [12]$$

$$\text{SCP ROA: } \Delta I^\alpha(\xi) = I_R^\alpha(\xi) - I_L^\alpha(\xi) \quad [13]$$

$$\text{DCP}_I \text{ ROA: } \Delta I_I(\xi) = I_R^R(\xi) - I_L^L(\xi) \quad [14]$$

$$\text{DCP}_{II} \text{ ROA: } \Delta I_{II}(\xi) = I_L^R(\xi) - I_R^L(\xi) \quad [15]$$

These different forms of ROA are illustrated in **Figure 1**. In the case of ICP- and SCP-ROA, the polarization state α is any fixed value. The standard choices are unpolarized, linearly polarized parallel to the scattering plane (depolarized) or linearly polarized perpendicular to the scattering plane (polarized). The standard scattering angles are

Figure 1 Energy level diagrams showing the transitions and polarization states associated with the definition of VCD and the various forms of ROA.

90° (right-angle scattering), 180° (backscattering), and 0° (forward scattering).

As an example of an ROA observable we present in **Figure 2** the backscattering DCP-ROA and Raman spectra of neat (–)- β -pinene in the region between 200 and 1700 cm^{-1} . The stereospecific structure of this molecule is given in the figure. The opposite enantiomer, the mirror-image molecule, would yield an ROA spectrum in which the signs of all the bands would be reversed, i.e. a ‘mirror-image’ ROA spectrum. Note that the ROA spectrum is approximately three orders of magnitude smaller than the corresponding Raman spectrum. Each parent Raman band has associated with it an ROA band of a particular sign and magnitude. There is no correlation between strong Raman bands and strong ROA bands.

General Theory of ROA

The general, complete theory of ROA embraces all possible polarization experiments, scattering geometries

Figure 2 DCP₁ Raman (a) and ROA (b) spectra for (–)-β-pinene.

and degrees of resonance Raman intensity enhancement. Because of this generality, the level of theory is complex and too lengthy to describe in the present context. Instead, we provide a verbal description of the formalism and refer the interested reader to a comprehensive review by Nafie and Che (1994) of the theory and measurement of ROA.

ROA and Raman intensity are proportional to the square of a tensor quantity, as expressed in eqn [1]. For Raman scattering only the square of the polarizability is needed, whereas ROA intensity arises from the product of the polarizability and an ROA tensor. The ROA tensors are approximately three orders of magnitude smaller than the polarizability, and hence an ROA spectrum is approximately three orders of magnitude smaller than its parent Raman spectrum. As noted above, the Greek subscripts of the tensor refer to the molecular axis system. However, for both Raman and ROA, linear combinations of products of tensors can be found that do not vary with the choice of the molecular coordinate frame. Such combinations are called invariants. All Raman intensities from samples of randomly oriented molecules can be expressed in terms of only three invariants, called the isotropic invariant, the symmetric anisotropy and the antisymmetric anisotropy, given by

$$\alpha^2 = \frac{1}{9} \text{Re}[(\tilde{\alpha}_{\alpha\alpha})^s (\tilde{\alpha}_{\beta\beta})^{s*}] \quad [16]$$

$$\beta_s(\alpha)^2 = \frac{1}{2} \text{Re}[3(\tilde{\alpha}_{\alpha\beta})^s (\tilde{\alpha}_{\alpha\beta})^{s*} - (\tilde{\alpha}_{\alpha\alpha})^s (\tilde{\alpha}_{\beta\beta})^{s*}] \quad [17]$$

$$\beta_a(\alpha)^2 = \frac{1}{2} \text{Re}[3(\tilde{\alpha}_{\alpha\beta})^a (\tilde{\alpha}_{\alpha\beta})^{a*}] \quad [18]$$

where the symmetric and antisymmetric forms of the polarizability tensors are given by

$$(\tilde{\alpha}_{\alpha\beta})^s = \frac{1}{2}[(\tilde{\alpha}_{\alpha\beta}) + (\tilde{\alpha}_{\beta\alpha})] \quad [19]$$

$$(\tilde{\alpha}_{\alpha\beta})^a = \frac{1}{2}[(\tilde{\alpha}_{\alpha\beta}) - (\tilde{\alpha}_{\beta\alpha})] \quad [20]$$

For ROA there are ten invariants, five associated with the Roman (font) tensors, $[\alpha G, \beta_s(\tilde{G})^2, \beta_a(\tilde{G})^2, \beta_s(\tilde{A})^2$ and $\beta_a(\tilde{A})^2]$ and five with the Arial tensors, $[\alpha G, \beta_s(\tilde{G})^2, \beta_a(\tilde{G})^2, \beta_s(\tilde{A})^2$ and $\beta_a(\tilde{A})^2]$. All of the different ROA experiments can be expressed in terms of these invariants. The ROA intensity for each experiment is expressed as a linear combination of some or all of the ten invariants. Although sets of experiments can be devised to isolate all three ordinary Raman invariants, only six distinct combinations of ROA invariants can be isolated.

Far from Resonance (FFR) Theory of ROA

The theory of ROA simplifies drastically in the limit, where the exciting laser radiation is far from the lowest

allowed excited state in the molecule, and the interaction of the light with the molecule is approximately the same for both the incident and the scattered radiation. This symmetry reduces the number of Raman invariants from three to two, the isotropic and (symmetric) anisotropic invariants, and the number of ROA invariants from ten to three. The relationships that reduces these thirteen Raman and ROA invariants to only five are

$$\beta_a(\alpha)^2, \beta_a(\tilde{G})^2, \beta_a(\tilde{A})^2, \beta_a(\tilde{G})^2, \beta_a(\tilde{A})^2 = 0 \quad [21]$$

$$\beta_s(\alpha)^2 = \beta(\alpha)^2 \quad [22]$$

$$\alpha G = -\alpha \mathbf{G} = \alpha G' \quad [23]$$

$$\beta_s(\tilde{G})^2 = -\beta_s(\tilde{\mathbf{G}})^2 = \beta(G')^2 \quad [24]$$

$$\beta_s(\tilde{A})^2 = \beta_s(\tilde{\mathbf{A}})^2 = \beta(A)^2 \quad [25]$$

where the following definition of the real and imaginary parts of complex tensor has been used

$$\tilde{T} = T - i T' \quad [26]$$

The equations for the two Raman invariants and three ROA invariants are

$$\alpha^2 = \frac{1}{9} \alpha_{\alpha\alpha} \alpha_{\beta\beta} \quad [27]$$

$$\beta(\alpha)^2 = \frac{1}{2} (3\alpha_{\alpha\beta} \alpha_{\alpha\beta} - \alpha_{\alpha\alpha} \alpha_{\beta\beta}) \quad [28]$$

$$\alpha G' = \frac{1}{9} \alpha_{\alpha\alpha} G'_{\beta\beta} \quad [29]$$

$$\beta(G')^2 = \frac{1}{2} (3\alpha_{\alpha\beta} G'_{\alpha\beta} - \alpha_{\alpha\alpha} G'_{\beta\beta}) \quad [30]$$

$$\beta(A)^2 = \frac{1}{2} \omega_0 \alpha_{\alpha\beta} \epsilon_{\alpha\gamma\delta} A_{\gamma\delta\beta} \quad [31]$$

where the FFR polarizability and optical activity tensors are given by

$$\tilde{\alpha}_{\alpha\beta} = \frac{2}{\hbar} \sum_{j \neq n} \frac{\omega_{jn}}{\omega_{jn}^2 - \omega_0^2} \text{Re}[\langle n | \hat{\mu}_\alpha | j \rangle \langle j | \hat{\mu}_\beta | n \rangle] \quad [32]$$

$$G'_{\alpha\beta} = \frac{-2}{\hbar} \sum_{j \neq n} \frac{\omega_0}{\omega_{jn}^2 - \omega_0^2} \text{Im}[\langle n | \hat{\mu}_\alpha | j \rangle \langle j | \hat{\mu}_\beta | n \rangle] \quad [33]$$

$$A_{\alpha\beta\gamma} = \frac{2}{\hbar} \sum_{j \neq n} \frac{\omega_{jn}}{\omega_{jn}^2 - \omega_0^2} \text{Re}[\langle n | \hat{\mu}_\alpha | j \rangle \langle j | \hat{\Theta}_{\beta\gamma} | n \rangle] \quad [34]$$

Using these invariants, we can write intensity expressions for ROA and Raman that cover all possible polarization modulations and scattering geometries in the FFR approximation. These expressions are:

$$I(R) - I(L) = \frac{8K}{c} [D_1 \alpha G' + D_2 \beta(G')^2 + D_3 \beta(A)^2] \quad [35]$$

$$I(R) + I(L) = 4K [D_4 \alpha^2 + D_5 \beta(\alpha)^2] \quad [36]$$

The values of the constants D_1 through to D_5 are given in **Table 1**.

Most of the ROA spectra measured to date have been for one of three kinds of experiments, right-angle depolarized ICP ROA, backscattering unpolarized ICP ROA, and backscattering DCP_I ROA. The early work on ROA was almost exclusively right-angle depolarized ICP ROA where the ROA and Raman intensity expressions from **Table 1** are

$$I_z^R(90^\circ) - I_z^L(90^\circ) = \frac{8K}{c} [3\beta(G')^2 - \beta(A)^2] \quad [37]$$

$$I_z^R(90^\circ) - I_z^L(90^\circ) = 4K [3\beta(\alpha)^2] \quad [38]$$

The corresponding polarized ICP ROA experiment included isotropic ROA invariants and was more difficult to measure without interference from polarization artifacts. In the late 1980s, the virtues of backscattering ROA were implemented on a routine basis. Two forms of backscattering ROA, each having their own theoretical or experimental advantages, have been used extensively. They are unpolarized backscattering ICP ROA, given by

$$I_u^R(180^\circ) - I_u^L(180^\circ) = \frac{8K}{c} [12\beta(G')^2 + 4\beta(A)^2] \quad [39]$$

$$I_u^R(180^\circ) + I_u^L(180^\circ) = 4K [45\alpha^2 + 7\beta(\alpha)^2] \quad [40]$$

and backscattering DCP_I ROA, given by

$$I_R^R(180^\circ) - I_L^L(180^\circ) = \frac{8K}{c} [12\beta(G')^2 - 4\beta(A)^2] \quad [41]$$

$$I_R^R(180^\circ) + I_L^L(180^\circ) = 4K [6\beta(\alpha)^2] \quad [42]$$

From these expressions, the advantages of ICP_u and DCP_I ROA in backscattering are apparent. The ROA invariants have a multiplicative advantage of 4 in backscattering and are additive rather than subtractive between the magnetic-dipole and electric-quadrupole ROA invariants. Comparing right-angle ICP_z and DCP_I Raman, both represent depolarized scattering with the backscattering stronger by a factor of 2. It can also be seen that the ROA expressions for backscattering ICP_u and DCP_I ROA are identical even though the ICP_u Raman intensity represents classical polarized Raman scattering and DCP_I Raman intensity the corresponding depolarized scattering. The additional Raman intensity in (ICP_u Raman $4K[45\alpha^2$

Table 1 Values of Raman and ROA invariant coefficients for the far-from-resonance ROA and Raman intensity expressions in eqn [41]

$+\beta(\alpha)^2$) carries no ROA intensity since this additional strongly polarized Raman intensity corresponds to DCP_{II} ROA which has no intensity in the FFR approximation as shown in Table 1. Thus backscattering DCP_I ROA discriminates against DCP_{II} ROA by analysing the circular polarization of the scattering light, whereas both of these intensities are present in ICP_u ROA which has no such discrimination.

Another interesting property of these expressions is the possibility of isolating the ROA spectra for the magnetic-dipole and electric-quadrupole ROA invariants. By proper experimental normalization of the depolarized Raman spectra given in eqns [38] and [42], the corresponding and suitably scaled ICP_z (90°) and DCP_I (180°) ROA spectra can be added and subtracted to yield these invariants. This has been accomplished for the molecule (+)-*trans*-pinane as shown in Figure 3.

Of the two backscattering ROA schemes predominantly in use these days, the ICP_u approach enjoys an advantage of experimental simplicity, while the DCP_I enjoys an advantage of higher ROA intensity per Raman intensity, particularly in regions of strongly polarized Raman bands where no such intensity enters the DCP_I Raman spectrum.

Single Electronic State Theory of Resonance ROA

When the frequency of the incident laser radiation in a Raman scattering experiment is in resonance with a single electronic state (SES), it is well known that strong enhancement of the Raman scattering occurs. This is because the denominator of the resonant term in the polarizability expression, eqn [4], approaches zero and

Figure 3 Depolarized Raman and ROA spectra of (+)-*trans*-pinane, showing the decomposition of right-angle depolarized ICP and DCP_I ROA into their magnetic-dipole and electric-quadrupole anisotropic ROA invariants.

the value of the polarizability can increase by several orders of magnitude. This resonance condition brings simplifying conditions to the theory of Raman scattering as it becomes known as resonance Raman (RR) scattering. Under conditions of strong resonance, the non-resonant terms can be dropped and the contributions of all other electronic states can be dropped as too small to consider. The Raman polarizability in eqn [4] for a 0 to 1 vibrational transition in the ground electronic state, g_0 to g_1 , becomes

$$(\tilde{\alpha}_{\alpha\beta})_{g_1, g_0} = \frac{1}{\hbar} \sum_v \frac{\langle g_1 | \hat{\mu}_\alpha | ev \rangle \langle ev | \hat{\mu}_\beta | g_0 \rangle}{\omega_{ev, g_0} - \omega_0 + i\Gamma_{ev}} \quad [43]$$

If the transition moment of the resonant electronic state is taken to lie in the z -direction, the general set of three Raman invariants and ten ROA invariants reduces effectively to only one Raman invariant and one ROA invariant, as

$$\alpha^2 = \frac{1}{9} |(\tilde{\alpha}_{zz})_{g_1, g_0}|^2 \quad [44]$$

$$\beta_s(\alpha)^2 = |(\tilde{\alpha}_{zz})_{g_1, g_0}|^2 \quad [45]$$

$$\alpha G = -\alpha \mathbf{G} = \frac{1}{9} \text{Im} \left[(\tilde{\alpha}_{zz})_{g_1, g_0} (\tilde{G}_{zz})_{g_1, g_0}^* \right] \quad [46]$$

$$\beta_s(\tilde{G})^2 = \beta_s(\tilde{\mathbf{G}})^2 = \text{Im} \left[(\tilde{\alpha}_{zz})_{g_1, g_0} (\tilde{G}_{zz})_{g_1, g_0}^* \right] \quad [47]$$

$$\beta_s(\tilde{A})^2 = \beta_s(\tilde{\mathbf{A}})^2 = 0 \quad [48]$$

$$\beta_a(\alpha)^2 = \beta_a(\tilde{G})^2 = \beta_a(\tilde{\mathbf{G}})^2 \beta_a(\tilde{A})^2 = \beta_a(\tilde{\mathbf{A}})^2 = 0 \quad [49]$$

In addition, it can be shown the Raman invariant is proportional to the square of the electronic absorption strength for the resonant electronic state, and the ROA is proportional to the product of the electronic circular dichroism (CD) and the electronic absorption strength of this state through the relationships,

$$|(\tilde{\alpha}_{zz})_{g_1, g_0}|^2 = (1/\hbar) |(\vec{\mu}_{eg}^0)|^4 U(\omega_0) \quad [50]$$

$$\begin{aligned} & \text{Im} \left[(\tilde{\alpha}_{zz})_{g_1, g_0} (\tilde{G}_{zz})_{g_1, g_0}^* \right] \\ &= (1/\hbar) |(\vec{\mu}_{eg}^0)|^2 \text{Im} \left[(\vec{\mu}_{eg}^0)^* \cdot (\vec{m}_{eg}^0)^* \right] U(\omega_0) \end{aligned} \quad [51]$$

where $\vec{\mu}_{eg}^0$ and $\vec{m}_{eg}^0$ are the electric-dipole and magnetic dipole transition moments, respectively, between the ground and resonant electronic states, respectively. In the case of resonance ROA in the SES limit, the most

efficient form of ROA is backscattering DCP_I where the intensity expressions are:

$$I_R^R(180^\circ) - I_L^L(180^\circ) = \frac{96K}{c} \text{Im}[(\tilde{\alpha}_{zz})_{g_1, g_0} (\tilde{G}_{zz})_{g_1, g_0}^*] \quad [52]$$

$$I_R^R(180^\circ) + I_L^L(180^\circ) = 24K |(\tilde{\alpha}_{zz})_{g_1, g_0}|^2 \quad [53]$$

From these relationships emerges a deep connection between RROA in the SES limit and the electronic CD of the resonant electronic state. Since the anisotropy ratio, g_{eg} , is defined as the ratio of the CD intensity to the parent intensity, the following expression is found

$$\frac{I_R^R(180^\circ) - I_L^L(180^\circ)}{I_R^R(180^\circ) + I_L^L(180^\circ)} = -\left(\frac{4}{c}\right) \frac{\text{Im}[(\vec{\mu}_{eg}^0) \cdot (\vec{m}_{eg}^0)]}{|(\vec{\mu}_{eg}^0)|^2} = -g_{eg} \quad [54]$$

The minus sign arises from the definition of ROA being right minus left circular polarization intensities, whereas the corresponding definition for CD is left minus right. Resonance ROA promises to open up new applications for ROA in the same way that resonance Raman spectroscopy extended the reach of Raman spectroscopy, particularly for biological applications.

Simple Models of ROA

Before the development of molecular orbital approaches to the calculation of ROA, a number of simple models of ROA were advanced to provide a conceptual basis for understanding ROA spectra. In various ways, these models arise from considering the polarizability of the molecule $\alpha_{\alpha\beta}$ as the sum of local polarizability units, such as those associated with bonds or atoms. While the polarizability and its individual local components are independent of the location of the origin of the molecule, the magnetic dipole and electric quadrupole ROA tensors do depend on this origin. In the FFR approximation, we can express these tensors in terms of local contributions as

$$\alpha_{\alpha\beta} = \sum_i \alpha_{i,\alpha\beta} \quad [55]$$

$$G'_{\alpha\beta} = \sum_i G'_{i,\alpha\beta} + \sum_i \frac{1}{2} \omega \varepsilon_{\beta\gamma\delta} R_{i,\alpha\delta} \alpha_{i,\alpha\beta} \quad [56]$$

$$\begin{aligned} A_{\alpha\beta\gamma} &= \sum_i A_{i,\alpha\beta\gamma} - \sum_i \frac{1}{2} [3R_{i,\beta} \alpha_{i,\alpha\delta} \\ &\quad + 3R_{i,\gamma} \alpha_{i,\alpha\beta} - 2R_{i,\delta} \alpha_{i,\alpha\delta} \delta_{\beta\gamma}] \end{aligned} \quad [57]$$

where $R_{i,\alpha}$ is the location of the i th polarizability unit relative to the origin. In the application of ROA models it is assumed that only the local polarizability units are non-zero and that contributions from the local ROA tensors, $G'_{i,\alpha\beta}$ and $A_{i,\alpha\beta\gamma}$,

are zero. The simplest of these models is the two-group model which describes the ROA from the two local symmetric polarizability groups in a molecule that are twisted in a chiral sense with respect to one another. ROA arises from the interference of the independent Raman scattering from each of these two groups. Only limited success has been achieved in the use of these models to understand the details of ROA spectra. For a quantitative understanding, one must use *ab initio* molecular orbital methods.

Ab Initio Calculations of ROA

Calculations of ROA using *ab initio* molecular orbital methods have been carried out. This has been achieved by starting with expressions for the polarizability and Rayleigh optical activity tensors in the zero-frequency limit of the FFR approximation as

$$\alpha_{\alpha\beta} = \frac{2}{\hbar} \sum_{j \neq n} \frac{\text{Re}[\langle n | \hat{\mu}_\alpha | j \rangle \langle j | \hat{\mu}_\beta | n \rangle]}{\omega_{jn}} \quad [58]$$

$$G'_{\alpha\beta} = -\frac{2\omega_0}{\hbar} \sum_{j \neq n} \frac{\text{Im}[\langle n | \hat{\mu}_\alpha | j \rangle \langle j | \hat{m}_\beta | n \rangle]}{\omega_{jn}^2} \quad [59]$$

$$A_{\alpha\beta\gamma} = \frac{2}{\hbar} \sum_{j \neq n} \frac{\text{Re}[\langle n | \hat{\mu}_\alpha | j \rangle \langle j | \hat{\Theta}_{\beta\gamma} | n \rangle]}{\omega_{jn}^2} \quad [60]$$

where the distinction between the initial and final states is not needed. ROA and Raman intensities can be obtained from these tensors by calculating their variation with the normal coordinates of vibrational motion. The method by which these tensors have been calculated is the field perturbation approach. The summation over all the excited states j can be avoided by substituting field perturbed wavefunctions in first-order perturbation theory for their non-perturbed counterparts as

$$\alpha_{\alpha\beta} = 2 \sum_{j \neq n} \text{Re}[\langle n | \hat{\mu}_\alpha | n'(E_\beta) \rangle] \quad [61]$$

$$G'_{\alpha\beta} = -2\hbar\omega_0 \text{Im}[\langle n'(E_\alpha) | n'(E_\beta) \rangle] \quad [62]$$

$$A_{\alpha\beta\gamma} = 2 \langle n | \hat{\Theta}_{\beta\gamma} | n'(E_\alpha) \rangle \quad [63]$$

Figure 4 Comparison of the experimentally measured and the *ab initio* calculated DCP₁ Raman and ROA spectra of L-alanine in aqueous solution.

where E_x and B_x are components of the electric and magnetic fields, and the prime on the wavefunction indicates the first derivative with respect to the field. In **Figure 4** we show the results of a comparison of *ab initio* ROA calculations for the molecule L-alanine in aqueous solution. A high degree of correspondence has been achieved between theory and experiment. This demonstrates that ROA can be calculated with success for small chiral molecules of biological significance.

Applications to Biological Molecules

Experimental measurements of ROA were first achieved in the mid-1970s. Since that time ROA spectra of many classes of molecules of biological significance have been published. These include terpenes, amino acids, sugars, carbohydrates, peptides, proteins, and nucleic acids. Through these studies, ROA can be seen to be a sensitive probe of the stereo-conformational detail of these molecules in their native environments.

As described in this article, the theory of ROA is rich in content, offering experimentalists many options in the measurements of ROA spectra. These include the wavelength of the exciting radiation and its proximity to allowed transitions to excited electronic states in the molecules. Also of importance is the polarization modulations scheme and the scattering geometry. Recent studies have established that the optimum polarization and scattering conditions for biological applications are either unpolarized ICP or in-phase DCP in back-scattering geometry.

The theoretical understanding of ROA is well in hand. The *ab initio* calculation of ROA intensities for simple molecules up to quite complex structures is now feasible to adequate accuracy. However, it is necessary to consider the dynamics and conformational populations of flexible molecules to appropriately represent experimental observations, thus increasing the computational complexity, albeit with increased ability to analyze conformational behaviour. Beyond the zero-frequency limit of the FFR approximation are the dynamic frequency limit, the near resonance conditions, and the strong resonance conditions involving more than one electronic state. As demonstrated above, the case of strong resonance with a single electronic state is trivial in that the ROA spectrum is completely predicted from the resonance Raman

spectrum and the electronic CD of the resonance electronic state.

The problem of extending ROA calculations to molecules of increasing complexity will accompany the steady increase in the power of computational calculations made possible by advances in the speed and memory capacity of computers.

With the realization of improvements in the measurements and theoretical calculation of intensities, ROA will assume a place of special importance among our spectroscopic probes of the structure and dynamics of molecules of biological interest.

Synopsis

Raman spectrometers are quite different from ‘ordinary’ spectrometers. In Raman spectra the very weak Raman lines are accompanied by the extremely strong Rayleigh line. The stray light of it produces a background in the spectrometer which may be more intense by orders of magnitude than the Raman lines. Therefore, a Raman spectrometer has to combine the elimination of the Rayleigh line with the spectral dispersion and isolation of the Raman lines. Additionally, the necessary resolving power of Raman spectrometers has to be considerably higher compared with ‘ordinary’, e.g. infrared spectrometers.

This article describes the elements of Raman spectrometers for routine analyses which are available commercially. Instruments designed only for special research

are not covered. Only spectrometers for ‘classical’ (linear) Raman scattering are mentioned, not those for observing resonance Raman scattering (RRS), surface-enhanced Raman scattering (SERS) and all nonlinear Raman techniques; they are described elsewhere in this Encyclopedia.

Rayleigh and Raman Scattering, the Raman Spectrum

Raman spectra are complementary to infrared spectra. Both are composed of lines (or bands of lines) which are images of the vibrations of molecules. The intensity of Raman lines represents the change of the molecular polarizability by a vibration, while the intensity of infrared lines represents the change of the molecular dipole moment (actually the square of the change of the molecular polarizability or the molecular dipole moment). The Raman lines are accompanied by the ‘Rayleigh line’ at the wavelength of the exciting radiation; its intensity is proportional to the square of the molecular polarizability. In addition, the intensity of this ‘unshifted’ line is enhanced further by the exciting radiation which is directly scattered at the surfaces of the particles of powders or at the windows of the sample cuvettes.

When monochromatic exciting radiation of light quanta $h\nu_0$ hits a molecule, an *elastic scattering process*, i.e. *Rayleigh scattering* of quanta having the energy $h\nu_0$ has the highest probability. The *inelastic scattering process*, during which vibrational energy $h\nu_s$ is exchanged with the molecules, has a much lower probability, and is called *Raman scattering*. It emits quanta of energy $(h\nu_0 \pm h\nu_s)$. At ambient temperature most molecules are in their vibrational ground state. According to Boltzmann’s law, a much smaller number are in their vibrationally excited state. Therefore, Raman scattering of quanta of energy $(h\nu_0 - h\nu_s)$ has much higher probability than the Raman scattering of quanta of energy $(h\nu_0 + h\nu_s)$. While studying fluorescence spectra Stokes, in 1852, postulated that the wavelength of light produced by photoluminescence, fluorescence or phosphorescence, is usually longer than that of the exciting light. In analogy, Raman lines are referred to as *Stokes lines* and *anti-Stokes lines*. Stokes lines are caused by the quanta of lower energy. Since their intensities are higher than those of anti-Stokes lines, only they are usually recorded as Raman spectrum. The line

intensities are usually drawn over the Raman shift, ν_s , in wavenumbers. The intensity ratio of Stokes and anti-Stokes lines of the same Raman shift allows, by employing the Boltzmann equation, the determination of the temperature of the sample under illumination.

The line width $\Delta\nu_s$ of the infrared and Raman lines is about the same. However, the necessary resolving power in the infrared spectrum for isolating an infrared line of width $\Delta\nu_s = 10 \text{ cm}^{-1}$ at a wavelength of $10 \mu\text{m}$ equivalent to a wavenumber of $\nu_s = 1000 \text{ cm}^{-1}$ is $R_{\text{IR}} = \nu_s/\Delta\nu_s = 100$. In the Raman spectrum excited with radiation of wavelength of 500 nm equivalent to $\Delta\nu_0 = 20\,000 \text{ cm}^{-1}$ the same vibration, at $\nu_s = 1000 \text{ cm}^{-1}$, is recorded at an absolute wave-number of $(\nu_0 - \nu_s) = 20\,000 - 1000 = 19\,000 \text{ cm}^{-1}$. Therefore, the necessary resolving power is $R_{\text{RA}} = 19\,000/10 = 1900$; this is larger by a factor of 19 than that necessary for recording the infrared line. This shows that Raman spectrometers have to supply a considerably large resolving power than infrared spectrometers.

The intensity of the Raman lines is given by the square of the change of the molecular polarizability by the vibrations. There is an analogy between the molecular polarizability and the molecular volume: vibrations that modulate the molecular volume are *Raman active*.

Figure 1a and **Figure 1b** show a potential energy diagram of a molecule with the vibrational ground state and one vibrational excited state. The direct transition can be observed (**Figure 1a**) by an absorption of a light quantum from the infrared spectral range. There is another way of exciting vibrational states (**Figure 1b**). The molecule is illuminated with light quanta of higher energy, from the visible or near-infrared range. These quanta are, on the one hand, scattered elastically, producing the Rayleigh line. On the other hand, the inelastic scattering process emits a light quantum of the energy of the exciting radiation which is reduced by

the vibrational energy. Therefore, infrared absorption and Raman scattering may produce—by different mechanisms—molecules in exactly the same vibrational excited state. The molecular symmetry may ‘allow’ or ‘forbid’ the activity in the Raman or infrared spectrum. An example is the *rule of mutual exclusion*: if a molecule has a centre of symmetry, then infrared active vibrations are forbidden in the Raman spectrum and vice versa.

For the observation of ‘classical’ Raman spectra exciting radiation from the visible part of the spectrum is used. When molecules have electronic energy levels, which can be excited by light quanta from the visible range of the spectrum, the molecules may undergo a transition into an electronic excited state. As a consequence the molecule emits fluorescence radiation (**Figure 1c**). Since this process has a quantum yield much larger than the Raman effect (of the order of 1 versus 10^{-6} – 10^{-11}) fluorescence is quite strong, much stronger than the Raman lines. Therefore, Raman lines are then overlaid by the strong (quasicontinuous) fluorescence radiation. This process may hinder the observation of Raman lines. The fluorescing molecules may be impurities, which can be removed by purification (by distillation, sublimation, or recrystallization). However, the fluorescing molecules may be normal constituents of the sample. This is true for all living cells or tissues. They have a chemical ‘machinery’, composed of enzymes, which are absorbing visible radiation. ‘Purification’ by destroying the fluorescing molecules will destroy the cells or tissues. The only way to prevent superimposing by fluorescence is excitation of Raman spectra with light quanta having a low energy which is not sufficient to excite electronic states (**Figure 1d**); this is done by using the Nd:YAG laser radiation at 1064 nm .

Figure 2 shows the Stokes and anti-Stokes part of the Raman spectrum of coumarin, excited by the Argon laser line at 514.5 nm . Three abscissa scales are drawn: the

Figure 1 Observation of the excitation of a vibrational state in the electronic ground state S_0 by (a) infrared absorption; (b) Raman scattering; excitation in the visible range ($\lambda = 488 \text{ nm}$); (c) absorption of the exciting radiation with subsequent fluorescence, (d) Raman scattering, excitation in the near-infrared range, ($\lambda = 1064 \text{ nm}$), the energy of the exciting light quanta is only 46% of that of (b), V = potential energy, QY = order of magnitude of the quantum yield, q = normal coordinate (describing the vibrational motion), S_0 = electronic ground level, S_1 = electronic excited level. Reproduced from Schrader B (ed.) (1995) *Infrared and Raman Spectroscopy*. Weinheim: VCH Publishers, with permission of VCH.

Figure 2 Raman spectrum of coumarin, excited with the radiation of the Ar^+ laser at $\lambda = 514.53 \text{ nm}$ equivalent to $\nu = 19430 \text{ cm}^{-1}$. Reproduced from Schrader B (ed.) (1995) *Infrared and Raman Spectroscopy*. Weinheim: VCH Publishers, with permission of VCH.

wavelength scale, the absolute wavenumber scale and the Raman shift, the energy difference between the exciting energy and the energy of the light quanta, scattered by the Raman effect. This is the only scale which is usually used to draw Raman spectra.

The Components of Raman Spectrometers

A Raman spectrometer analyses the radiation scattered by molecules, when they are illuminated with monochromatic exciting radiation. The scattered radiation is composed of the strong Rayleigh line and the very weak Raman lines. The Rayleigh line has a radiant power that may exceed that of the Raman lines by about 10^6 up to 10^{15} . The electric signal S produced by a radiation detector is proportional to the radiant power $\Phi(W)$, received by the detector. A Raman spectrometer has to facilitate recording of the Raman lines with a high signal-to-noise ratio (S/N) sufficiently resolved.

The radiant power transmitted Φ by any optical instrument is given by

$$\Phi = LG\tau$$

Here, L describes the *radiance* of the radiation source, power per area and solid angle ($\text{W cm}^{-2} \text{ sr}^{-1}$), G is the *optical conductance*, solid angle times area (sr cm^2), and τ represents the *transmission* of the whole system. In order to record Raman spectra with a large S/N , all factors, L , G and τ , have to be maximal. L is optimized by appropriate sample arrangements. G is maximal when the spectrometer uses a maximal area of the essential elements

(the prism or grating or the beam splitter of an interferometer and the entrance aperture). A maximal value of τ is guaranteed by a proper design of the instrument, especially by antireflection coating of all glass/air interfaces and by a maximal reflectivity of all mirrors. As an approximation the optical conductance of a pair of succeeding elements of a spectrometer constructed by apertures, lenses or mirrors having an area F_i , $i = 1$ and 2 at distance of a_{12} is given by

$$G \approx F_1 F_2 / a_{12}^2$$

The flux through a spectrometer is appropriately described by

$$\Phi_v = L_v G_v (\Delta v^2) \tau$$

Here the subscript v stands for 'per wavenumber'. L_v , the spectral radiance, is a property of the radiation source, G_v the spectral optical conductance and Δv the bandwidth of the instrument (in wavenumber units), τ is the overall transmission factor of the entire instrument.

In every well-constructed optical instrument the optical conductance of all pairs of succeeding elements should be the same. The overall optical conductance of any instrument is given by the smallest optical conductance of any succeeding pair of elements.

The practical resolving power is given by the ratio of the wavenumber (or wavelength) and the bandwidth. Its upper limit is the theoretical resolving power, R_0 , determined by the properties of the dispersive elements, the number of grating rules in a grating spectrometer or the pathlength difference of the interfering rays in an interferometer (Figures 3 and 4).

Figure 3 The main components of a grating spectrometer: N is the number of interfering rays, given by the number of rules; S_0 is the halfwidth of the diffraction pattern of the collimator lens with diameter D' and focal length f , which determines the 'optimal' slit width, h is the slit length. Reproduced from Schrader B (ed.) (1995) *Infrared and Raman Spectroscopy*. Weinheim: VCH Publishers, with permission of VCH.

Figure 4 The significant features of an interferometer: Δl displacement of the moving mirror, $2r$ diameter of the Jacquinot stop. Reproduced from Schrader B (ed.) (1995) *Infrared and Raman Spectroscopy*. Weinheim: VCH Publishers, with permission of VCH.

The ratio of the spectral optical conductance of an interferometer, compared to a grating spectrometer (the Jacquinot advantage) is given by

$$G_v^I/G_v^G \approx 2\pi f/b$$

with f the focal length of the collimator and b , the slit height of the grating spectrometer. For spectrometers with the same beam area at the interferometer and the grating this factor amounts to about 500. However, common interferometers generally have a smaller beam area than grating instruments; therefore the Jacquinot advantage of actual instruments is of the order of 100. This can be compensated by using array detectors with grating polychromators, employing the multichannel advantage.

Light Sources

Raman spectroscopy began in 1928 by using the lines of a mercury discharge lamp at 435.8 or 404.7 nm as the exciting radiation. Since 1960 lasers have been available as ideal monochromatic sources of exciting radiation. The ruby laser (694.0 nm), HeNe-laser (632.8 nm), Ar^+ laser (488.0 and 514.5 nm), the GaAs diode laser (780 nm) and the Nd:YAG laser (1064 nm) are mainly employed. The light flux necessary for recording of Raman spectra is of the order 10 up to 1000 mW.

All laser lines in the visible range of the spectrum, especially the Ar^+ laser lines, but also the line at 780 nm, may excite fluorescence spectra, overlaying the Raman spectra. Excitation by radiation with longer wavelengths reduces the danger of fluorescence. With the exciting radiation of 1064 nm the minimal probability of fluorescence is reached.

Sample Arrangements

'Classical' Raman arrangements use the Raman radiation which is emitted at an angle of about 90° relatively to the direction of the exciting radiations (90° arrangement). This is the straightforward arrangement to illuminate the entrance slit of a grating spectrometer by the Raman radiation excited by a focused laser beam in a liquid. However, when interferometers having a circular entrance aperture are employed it has been proven to be superior to analyse the Raman intensity emitted at about 180° to the exciting radiation (180° or backscattering, arrangement).

In order to record Raman spectra of a sufficiently large S/N in an acceptable time the spectral radiance of the sample has to be maximal. Since Raman spectra are very weak and an excessive large power of the exciting radiation could destroy the sample, sample arrangements have to be designed very carefully. In particular, the ratio of the usable intensity of the Raman radiation at the entrance aperture of a spectrometer versus the intensity of the available exciting radiation, the figure of merit of the sample cell, has to be optimized. This can be done, on the one hand, by observing the Raman radiation produced from a large thickness of the sample, for instance with *end-on* capillary cells (Figure 5d) or, on the other hand, by employing different kinds of multiple reflection cells. The largest part of the exciting radiation in cells as in Figure 5a is not used for producing Raman radiation scattered in a direction to the spectrometer, but rather in other directions. Since the exciting radiation just passes the sample once, more than 99% of the exciting radiation is lost. With spherical mirrors surrounding the sample cell this radiation is reflected back to the sample. Also, the Raman radiation, which is not taken up by the spectrometer, is reflected back to the sample. This is done by cells as shown in Figure 5b. A 'notch filter' just behind

Figure 5 Sample arrangements for Raman spectroscopy: (a) rectangular cell; (b) spherical cell for liquids and powders which are in a melting point capillary at the centre of the sphere with a reflecting surface; (c) liquid in an NMR tube, the axis of which has angle of 45° relative to the axis of the entrance optics. The cuvettes (a)–(c) may be used in a 90° or a 180° arrangement; (d) light pipe cuvette; (e) arrangement for solids or surface layers: the sample is placed upon a block of aluminium or stainless steel with a polished conical indentation, providing a multiple reflection arrangement; (f) tablet with a cone-shaped bore; (g) arrangement for Raman spectroscopy of powders in 0° and 180° arrangement, the half-spheres have a reflecting surface which reflects the exciting and Raman radiation back to the sample increasing the usable Raman intensity; (h) same as (g), but one half-sphere is exchanged against a Weierstrass lens (Weierstrass 1856), which collects the radiation emitted into a solid angle of $\sim 2\pi$; (i) sample head for a two-way bundle of optical fibres for spectroscopy of liquids or powders. The head can be introduced directly into the sample; it is protected by a cover in order to prevent sticking and pyrolysis of the sample at the central fibre which transports the exciting radiation from the laser to the sample. Reproduced from Schrader B (ed.) (1995) *Infrared and Raman Spectroscopy*. Weinheim: VCH Publishers, with permission of VCH.

the entrance optics reflects the exciting radiation emerging in the direction as the Raman radiation recorded by the spectrometer, while it transmits the Raman radiation. When the overall reflectivity of the multiple reflection cell for the exciting radiation is ρ , the increase of the observable Raman intensity is given by $I = 1/(1-\rho)$. With $\rho = 90\%$, the Raman intensity will be larger by a factor of 10, compared to the original intensity. Since also the intensity of the effective Raman radiation is increased by the multiple reflection cell, the intensity of the Raman spectrum increases further (to a maximum of $\bar{F}$). **Figure 5** gives examples of different sample cells for liquids and powders which have been used successfully. Rectangular sample cells, which are supplied with most Raman spectrometers, have a very small figure of merit, since they do not employ multiple reflection enhancement or the observation of an increased effective thickness of the sample.

In **Figure 5i** an arrangement for investigation of remote samples by fibre optics is shown. The high transmittance of optical fibres in the NIR range makes possible the recording of Raman spectra of samples, which are located up to several hundred metres away from the spectrometer. The quartz fibres, developed for telecommunications, have a large transmission in the spectral range of Raman spectra excited in the NIR—more than 80% per km! One fibre transports the exciting radiation from the laser to the sample; a second fibre or fibre bundle transports the Raman radiation from the sample to the spectrometer. However, it cannot be

avoided that the Raman lines of quartz are excited in both fibres. Therefore, the sample head has to be combined with a transmission filter which eliminates, on the one hand, the Raman line of the quartz from the exciting radiation and, on the other hand, the exciting radiation coming back from the sample on the way to the spectrometer (see the next section: Rayleigh filters). Some companies supply such sample heads which allow remote product or production control.

The laser radiation can be focused to a diameter of the order of a few multiples of its wavelength. Therefore, even by using the normal entrance optics of the spectrometer one can investigate Raman spectra of micro samples. However, in order to be able to exactly adjust the area from which the Raman spectrum is taken, common microscopes, able to adjust the sample by observation with visible light, are modified for the excitation and observation of Raman spectra. Such microscopes may even allow confocal observation with 3-dimensional spatial resolution. It must be remembered that the optical conductance of microscopes is quite small; therefore much longer observation times are needed for Raman spectroscopy of micro samples. This cannot be compensated by a larger power of the laser radiation, since this may then overheat the sample.

Rayleigh Filters

A spectrometer set to pass radiation of a particular wavelength band always has a small amount of stray

radiation of other wavelengths. The Rayleigh line is stronger by 10^6 – 10^{12} than the Raman lines. In ordinary spectrometers the Rayleigh scattering produces stray radiation, which conceals the Raman spectrum completely. Therefore, the Rayleigh radiation has to be eliminated in order to record Raman lines with a maximal signal/background ratio. Different principles are employed for this purpose:

Absorption filters composed of solutions with appropriate absorption bands or glass filters with absorption edges are able to absorb the spectral band of the Rayleigh radiation. Especially interesting is the elimination of the exciting line by atomic absorption of the same element, which produces the exciting radiation. Rasetti, in 1930, used the low-pressure mercury arc to excite rotational Raman spectra of gases with the mercury resonance line at 253.6 nm. With a drop of mercury in the spectrograph he could completely absorb the Rayleigh radiation. Similar procedures use the resonance absorption of rubidium and caesium.

Interference line filters reflect the whole spectrum with a high reflectivity except for the spectral line where the filter has the largest transmittance. The Rayleigh line intensity can thus be reduced by reflection on the filter. Combinations of such filters in a row make up a very efficient Rayleigh filter.

The same filters are employed satisfactorily to reduce the unwanted plasma lines of the laser radiation for the excitation of the Raman spectra; also, Raman lines of the optical fibres transporting the exciting radiation to the sample can be eliminated using interference transmission filters.

Volume holographic optical elements, developed for military uses, are successfully applied for Raman spectroscopy: a so-called notch filter reflects a laser line virtually completely, its intensity is reduced by >6 orders of magnitude, with a transmission of about 70% at the other wavelengths.

Holographic laser bandpass filters reflect the laser radiation by $>90\%$ at an angle of exactly 90° while reducing the intensity of all unwanted plasma or Raman lines (of an optical fibre) considerably.

A similar construction, a so-called Holoplex transmission grating, disperses the Raman spectrum for recording on CCDs (charge-coupled devices), which are very sensitive detector arrays. They can be fabricated with 2-dimensional dispersion allowing the instantaneous recording of several spectral channels on a 2-dimensional CCD detector as for an echelle spectrograph.

Dispersive Mono- and Polychromators, Interferometers

When illuminated with monochromatic radiation a single monochromator usually shows continuous stray light of

the order of 10^{-5} of the intensity of the monochromatic radiation. Therefore, 2 or 3 monochromators in series combined with additive dispersion reduce the stray radiation by about 10^{-10} or 10^{-15} , respectively. However, the intensity of the Raman lines is also reduced when passing a monochromator: since every monochromator has a transmittance only of about 30%, this means that a double monochromator has only a transmittance of 9%, and a triple monochromator of 2.7%. Such monochromators are usually very voluminous and expensive. However, they are widely used for recording of Raman spectra with single detectors (photomultipliers).

When array detectors are used to record simultaneously the whole spectrum, or parts of it, three monochromators are used in a special arrangement. The first two monochromators are combined in a subtractive arrangement. A diaphragm at the middle slit blocks out the Rayleigh line. The third grating instrument acts as a polychromator; it produces a spectrum directly upon the elements (pixels) of a CCD.

Interferometers record an interferogram of a spectrum. By applying the Fourier transformation, the original spectrum is calculated. Jacquinot pointed out in 1954 that interferometers have a considerably higher optical conductance, by a factor of 100–500, compared to prism or grating spectrometers. Interferometers make use of the *multiplex advantage* when compared to dispersive spectrometers. By recording all channels simultaneously with the same single detector, the detector noise is therefore distributed over all spectral channels. It is not recorded at every spectral channel separately as for prism or grating spectrometers. This increases the S/N considerably.

For recording the weak Raman spectrum excited by the Nd:YAG laser line at 1064 nm, interferometers are successfully used. They have to be combined with very powerful Rayleigh filters. The quantum noise of every strong line is distributed over the whole interferogram. By Fourier transformation it is distributed as white noise over the whole spectrum. To avoid this *multiplex disadvantage* all strong lines have to be removed from the spectrum to be analysed.

Detectors

The first generation of Raman spectroscopists used photoplates for the recording of Raman spectra. Later, photomultipliers were used as very powerful single channel detectors at the exit slit of a monochromator recording the Raman spectrum sequentially.

They are now being replaced by metal oxide semiconductors where charge produced by light quanta is stored in a small area, a pixel. Arrays composed of many independent pixels store the charge pattern corresponding to the irradiation pattern. These arrays of CCDs

can be linear or two-dimensional, thus storing spectra or images of the sample. Since the number of pixels is limited (usually to about 1024 in a row) spectra can be recorded either *completely, in low resolution, or in high resolution sequentially*. Combined with an echelle spectrograph several channels representing different spectral orders of grating can be recorded simultaneously in high resolution.

Since the spectral information 'seen' by the individual pixel is recorded simultaneously, an array with n pixels is equivalent to n spectrometers working separately or one spectrometer working n times. Simultaneous recording of n pixels provides the *multichannel advantage*.

Cooling reduces thermal noise of CCD detectors, so that integration times may be long, up to days. Thus, very faint Raman lines can be recorded.

Interferometers work with single detectors. For the NIR range InGaAs or Ge semiconductor detectors are used. They have to be extremely sensitive, since the intensity of the Raman lines decreases with the fourth power of its absolute frequency (the ν^4 factor). In order to reduce their thermal noise they are cooled by Peltier elements or liquid nitrogen.

Complete Raman Spectrometers

Complete Raman spectrometers are produced by several companies. Due to limited space and to the fact that the market is changing continuously, only the names of the main producers can be given here: Andor, Bio-Rad, Bruker*, Dilor, Instruments S.A. Jobin-Yvon, Kaiser Optical Systems, Nicolet*, Ocean Optics, Perkin-Elmer*, Renishaw, Sentronik, Spex. The companies marked

with a* supply Raman spectrometers with excitation at 1064 nm able to record 'fluorescence-free' Raman spectra. Most companies supply Raman microscopes.

Symbols

E	electric field
E_m	energy of level m
g_0	degeneracy of ground state
g_1	degeneracy of upper level
h	Planck's constant
I	intensity
k	Boltzmann's constant
Q	Nuclear coordinate
t	time
T	absolute temperature
α	electronic polarizability
$\bar{\alpha}$	mean polarizability
γ	polarizability anisotropy
Γ_r	damping of level r
ϵ_0	vacuum permittivity
θ	scattering angle
λ	normal mode of vibration
μ^{ind}	induced electric dipole moment
μ^{r0}	transition dipole moment
ν	frequency of incident radiation
ν'	frequency of emitted radiation
ν_S	Stokes frequency
ν_{AS}	anti-Stokes frequency
ρ	depolarization ratio
ϕ_0	wavefunction with energy E_0
χ	vibrational wavefunction

Rayleigh scattering, the commonplace phenomenon which accounts for the brightness of the sky (amongst many other familiar aspects of the world we inhabit) and the Raman effect, a weaker analogue seen only at high intensities, are closely similar processes in which light is scattered by atoms or molecules. The interactions each entails differ in that the Rayleigh process is technically *elastic* whilst its Raman counterpart is *inelastic* – all of the features in which the two processes significantly differ owe their origin to that fundamental difference in the energetics. Matter responsible for Rayleigh scattering neither loses nor gains energy thereby – and so the scattered light has the same frequency as the radiation from which it is produced. However, atoms or molecules engaged in Raman scattering either gain or lose energy in

the process, so that the frequency of the emergent light differs from that impinging on them – by conservation of energy, the emergent light has either a lower or higher frequency, respectively, as a result. The two types of Raman process, known as Stokes and anti-Stokes, are illustrated schematically in the energy level or ladder diagrams of **Figure 1a** and **Figure 1b**; the Stokes process results in a molecular transition to a state of higher energy, and its anti-Stokes counterpart is a transition to a state of lower energy. Rayleigh scattering processes are represented by **Figure 1c** and **Figure 1d**.

A simple picture widely used for didactic purposes portrays Rayleigh scattering in terms of the electric field of impinging radiation generating, through its interaction with the electron cloud of the scattering molecule, an outgoing field that oscillates at the same frequency. The Raman process is considered to be the generation of an emergent field modulated by molecular vibrations. However, theory cast at that level is of severely limited value – it fails, for example, to address the relative magnitudes of the Stokes and anti-Stokes Raman signals, and it is not well suited to processes involving electronic transitions. To fully understand those aspects we have to look further into the theory of the fundamental interactions involved in the scattering of light.

Figure 1 Energy level diagrams illustrating Raman and Rayleigh scattering, with incoming radiation on the left, scattered radiation emergent on the right. Only energy levels directly involved are depicted: (a) Stokes Raman transition; (b) anti-Stokes Raman transition; (c) and (d) Rayleigh scattering.

Rayleigh Scattering

The blue of the sky attests to more efficient Rayleigh scattering at the higher frequency, shorter wavelength end of the visible spectrum – the familiar red sky before dusk and at dawn manifesting the loss of bluer light to skies in other parts of the world. In fact the efficiency of scattering has a cubic dependence on the optical frequency, the scattered intensity having a fourth power dependence because the photon energy itself then enters into the equation. Although it is a moot point for Rayleigh scattering, these dependences actually relate to the frequency of the scattered rather than the incident light, a distinction which nonetheless becomes significant in the case of Raman scattering where the same power laws apply.

The mechanism for Rayleigh scattering entails the electronic polarizability α of the molecules of the sample. The polarizability itself is essentially a measure of how easily the molecular charge distribution is shifted through its interaction with electromagnetic radiation. At simplest, and in an isotropic system such as an atom, the polarizability is a quantity which represents the constant of proportionality between the electric field E of the radiation and the electric dipole moment it induces in the same direction, $\mu_x^{\text{ind}} = \alpha E$. A further guide to its nature can be gained from the polarizability volume, $\alpha' = \alpha/4\pi\epsilon_0$ (where ϵ_0 is the vacuum permittivity), which casts this constant in units of volume and often yields a value similar in magnitude to the molecular volume. This correctly suggests that systems such as large atoms and aromatic molecules tend to have large polarizabilities. Nonetheless in all but the highest symmetry molecules the ease of charge displacement within the molecule varies with direction, so that in general the induced dipole moment is not parallel with the applied electric field, but slanted towards the direction of least resistance. Then the polarizability is a second rank tensor and we have

$$\mu_i^{\text{ind}} = \sum_j \alpha_{ij} E_j \quad [1]$$

where i and j represent Cartesian coordinates – for example, the dipole moment induced in the x -direction is determined by $\mu_x^{\text{ind}} = \alpha_{xx}E_x + \alpha_{xy}E_y + \alpha_{xz}E_z$.

It is the development of a fully quantum theoretical depiction of scattering at the molecular level which leads to the detailed structure of the electronic polarizability. Here, each Rayleigh (or Raman) scattering event is understood as involving the absorption of one photon of the incoming radiation, accompanied by the emission of one photon. It is important to recognize that the absorption and emission take place together in one concerted process; there is no measurable time delay

between the two events. The energy–time uncertainty relation $\Delta E \Delta t \geq \hbar/2\pi$ allows for each process to take place even when there is no energy level to match the energy of the absorbed photon, as indicated by the absence of any level at the upper end of the arrows in **Figure 1**. In other words the absorption does not populate a real intermediate state, since it is accompanied by emission. Thus it is, for example, that Rayleigh scattering of visible light takes place even in transparent media.

Despite their widespread adoption and utility, energy diagrams such as **Figure 1** are potentially misleading for any such processes involving the concerted absorption and/or emission of more than one photon – for in this case they incorrectly suggest that emission takes place subsequent to absorption. All such processes are best described with the aid of time-ordered diagrams which symbolically represent such interactions as a series of photon absorptions and emissions, and which lead to a more correct theoretical representation. Both for Rayleigh and Raman scattering there are two possible sequences, depending on whether the absorption or the emission comes first. These two cases are illustrated by the time-ordered diagrams of **Figure 2a** and **Figure 2b**, in which the vertical line represents the successive states of the molecule, and the wavy lines photons, the sequence of interactions being read upwards. Thus in both diagrams the molecular progress from an initial state m to a final state n proceeds via an intermediate state r ; in (a) the transition from m to r is accompanied by absorption of a photon $h\nu$ from the incident beam, and the transition from r to n by emission of a photon $h\nu'$; in (b) this ordering of absorption and emission is reversed. In reality these processes are not separable; the diagrams simply assist development of the theory. Therefore, although the overall process is subject to energy conservation, i.e. $E_m + h\nu = E_n + h\nu'$, energy need not be conserved in the

Figure 2 Time-ordered diagrams for light scattering, with time progressing upwards. Taken together, each applies to both Rayleigh and Raman processes; in the Rayleigh case the initial state m and the final state n of the molecule become the same, and $\nu' = \nu$.

individual absorption and emission stages. For this reason the state r is often referred to as a virtual state, and all possible energy levels must be taken into account.

Interpreting the time-ordered diagrams of **Figure 2** by the rules with which they are associated, and given that the states m and n can be identified with the electronic ground state with wavefunction φ_0 and energy E_0 , the following result for the polarizability is obtained:

$$\alpha_{ij} = \sum_r \left[\frac{\langle \varphi_0 | \hat{\mu}_i | \varphi_r \rangle \langle \varphi_r | \hat{\mu}_j | \varphi_0 \rangle}{E_r - E_0 - b\nu - ib\Gamma_r} + \frac{\langle \varphi_0 | \hat{\mu}_j | \varphi_r \rangle \langle \varphi_r | \hat{\mu}_i | \varphi_0 \rangle}{E_r - E_0 - b\nu - ib\Gamma_r} \right] \quad [2]$$

where the two complete terms on the left and right of the plus sign correspond directly to **Figure 2a** and **Figure 2b** respectively. In eqn [2], φ_r is the wavefunction of state r with energy E_r and line width $\frac{1}{2}\Gamma_r$ and $\hat{\mu}_i$ is the i th component of the electric dipole moment operator. In frequency regions close to an optical absorption band, one of the states in the summation over r will be such that $E_r - E_0 \approx b\nu$, so that the first term of eqn [2] will have a small denominator, approximating to the line width factor $-ib\Gamma_r$, and the term as a whole – see **Figure 2a** – will overwhelm all else. However, in more common off-resonant circumstances the line width factor can be neglected in each denominator. Moreover for most electronic states the Dirac brackets $\langle \varphi_0, | \hat{\mu}_i | \varphi_r \rangle$ and $\langle \varphi_r, | \hat{\mu}_i | \varphi_0 \rangle$ are identical and can be expressed more concisely as components of the transition dipole moment μ^{r0} . Again for conciseness, defining $b\nu_{r0} = E_r - E_0$, eqn [2] then finally reduces to

$$\alpha_{ij} \approx \frac{2}{b} \sum_r \left(\frac{\nu_{r0}}{\nu_{r0}^2 - \nu^2} \right) \mu_i^{r0} \mu_j^{r0} \quad [3]$$

Rayleigh scattering generally produces radiation with a changed polarization state; polarized incident light is to some extent depolarized by the process whilst unpolarized light is to some extent polarized. Both effects are normally characterized by a depolarization ratio defined as the intensity ratio of plane polarized components of the scattered light. For right-angled scattering of light polarized in the z -direction and incoming along the y -direction, as shown in **Figure 3**, the depolarization ratio ρ_l of light scattered in the x -direction is calculated as

$$\rho_l = I(z \rightarrow y) / I(z \rightarrow z) \quad [4]$$

where the subscript on the ρ denotes linear polarization (synonymous with plane polarization). The value of ρ_l depends on the molecules responsible for the scattering and is directly expressible in terms of polarizability parameters. Specifically, if we define the polarizability

Figure 3 Scattering geometry for the usual measurement of depolarization ratios; incident radiation is z -polarized and light scattered at right-angles is resolved for its y - and z -polarization components.

mean $\bar{\alpha}$ and anisotropy γ through

$$\bar{\alpha} = \frac{1}{3} \sum_{i=x,y,z} \alpha_{ii}; \quad \gamma^2 = \frac{9}{2} \bar{\alpha}^2 + \frac{3}{2} \sum_{i=x,y,z} \sum_{j=x,y,z} \alpha_{ij}^2 \quad [5]$$

then for scattering by a gas or liquid we find

$$\rho_l = \frac{3\gamma^2}{4\gamma^2 + 45\bar{\alpha}^2} \quad [6]$$

with a value in the interval (0, 0.75). The lower limit corresponds to scattering with full retention of linear polarization and corresponds to $\gamma^2 = 0$, a case which occurs only for molecules of very high symmetry. Although introduced here for right-angled scattering, the above result is in fact independent of scattering angle. In contrast the extent of polarization introduced by the scattering of unpolarized light is an angle-dependent quantity. For right-angled scattering where the effect is largest, the corresponding ‘depolarization ratio’ is given as

$$\rho_n = I(n \rightarrow y) / I(n \rightarrow z) \quad [7]$$

(where the subscript of the ρ stands for natural), giving

$$\rho_n = \frac{6\gamma^2}{7\gamma^2 + 45\bar{\alpha}^2} \quad [8]$$

For scattering at other angles θ (where $\theta = 0$ relates to forward scattering) the result can be written as

$$\rho_n(\theta) = \cos^2 \theta + \rho_n \sin^2 \theta \quad [9]$$

The angle dependence of the polarization which Rayleigh scattering confers on unpolarized light is immediately evident on viewing a clear daytime sky through polarizing spectacles.

The Raman Effect

The Raman effect was one of the first processes whose explanation, largely through the work of Placzek in 1934, exploited and vindicated the still nascent quantum theory. As for Rayleigh scattering, each scattering event involves concerted processes of photon absorption and emission, without the need for an energy level to match the absorbed photon. The difference is that as a result of this process, the scatterer undergoes an overall transition from one energy level to another, as depicted in **Figure 1a** and **Figure 1b**. The Raman effect is a very weak phenomenon; typically only one incident photon in $\sim 10^7$ produces a Raman transition, and observation of the effect thus requires a very intense source of light.

Raman scattering generally involves transitions amongst energy levels that are separated by much less than the photon energy of the incident light. The two levels, denoted by E_0 and E_1 in **Figure 1**, for example, are most often vibrational levels, whilst the energies of the absorbed and emitted photons are commonly in (or near to) the visible range – hence the effect provides the facility for obtaining vibrational spectra using visible light. In general the Stokes Raman transition from level E_0 to E_1 results in scattering of a frequency given by

$$v_s = v - \Delta E/h \quad [10]$$

where $\Delta E = (E_1 - E_0)$, and the corresponding anti-Stokes transition from E_1 to E_0 produces a frequency

$$v_{AS} = v + \Delta E/h \quad [11]$$

Thus each allowed Raman coupling generally produces two frequencies in the spectrum of scattered light, shifted to the negative and positive sides of the dominant Rayleigh line by the same amount, $\Delta v = \Delta E/h$. For this reason Raman spectroscopy is concerned with measurements of frequency shifts, rather than absolute frequencies. In most cases a number of Raman transitions can take place, involving various molecular energy levels, and the spectrum of scattered light contains a range of frequencies shifted away from the irradiation frequency. In the particular case of vibrational Raman transitions, the shifts can be identified with vibrational frequencies.

Although each Stokes line and its anti-Stokes counterpart are equally separated from the Rayleigh line, they are not of equal intensity. This is because the intensity of each transition is proportional to the population of the energy level from which the transition originates; under equilibrium conditions the ratio of populations is given by the Boltzmann distribution. With the fourth-power dependence on the scattering frequency, the ratio of intensities of the Stokes line and its anti-Stokes partner in a

Raman spectrum is given by

$$I_{AS}/I_S = \{(v + \Delta v)/(v - \Delta v)\}^4 (g_1/g_0) \exp(-b\Delta v/kT) \quad [12]$$

where g_0 is the degeneracy of the ground state and g_1 that of the upper level – and hence the anti-Stokes line is almost invariably weaker in intensity. The dependence of this ratio on the absolute temperature T can, for example, be employed as a means of flame thermometry. However, since the Stokes and anti-Stokes lines give precisely the same information on molecular frequencies, it is usually only the stronger (Stokes) part of the spectrum that is recorded.

A development of detailed theory, again based on the time-ordered diagrams of **Figure 2**, establishes the dependence of Raman scattering on a transition tensor which takes on the same role as the polarizability in Rayleigh scattering. Once the usual Born–Oppenheimer separation of electronic and vibrational wavefunctions has been effected, then for the vibrational Raman transition $v \rightarrow v'$ involving a normal mode of vibration λ , this tensor takes the form

$$\alpha_{ij}^{v'v\lambda} = \sum_{r,v''(\mu)} \left[\frac{\langle \chi_0^{v'\lambda} | \langle \varphi_0 | \hat{\mu}_i | \varphi_r \rangle | \chi_r^{v''\mu} \rangle \langle \chi_r^{v''\mu} | \langle \varphi_r | \hat{\mu}_j | \varphi_0 \rangle | \chi_0^{v\lambda} \rangle}{E_r^{v''\mu} - E_0^{v\lambda} - h\nu - ib\Gamma_r^{v''\mu}} + \frac{\langle \chi_0^{v\lambda} | \langle \varphi_0 | \hat{\mu}_j | \varphi_r \rangle | \chi_r^{v''\mu} \rangle \langle \chi_r^{v''\mu} | \langle \varphi_r | \hat{\mu}_i | \varphi_0 \rangle | \chi_0^{v\lambda} \rangle}{E_r^{v''\mu} - E_0^{v\lambda} - h\nu - ib\Gamma_r^{v''\mu}} \right] \quad [13]$$

where, for example, the vibrational wavefunction $\chi_{r\mu}^v$ denotes a state with a quantum number v'' in the vibrational mode μ , within the set of levels associated with electronic state r . Here also $E_r^{v''\mu}$ and $\Gamma_r^{v''\mu}$ relate to the total (electronic plus vibrational) energy and the damping, respectively, of that state. Away from resonance, in other words when using frequencies ν well removed from any optical absorption bands, then the vibrational energy contributions in each denominator term of eqn [13] can safely be neglected. Then, using the completeness relation of quantum mechanics, the $|\chi_r^{v''\mu}\rangle \langle \chi_r^{v''\mu}|$ sum can be effected to give

$$\begin{aligned} \alpha_{ij}^{v'v\lambda} &= \sum_r \left[\frac{\langle \chi_0^{v'\lambda} | \langle \varphi_0 | \hat{\mu}_i | \varphi_r \rangle \langle \varphi_r | \hat{\mu}_j | \varphi_0 \rangle | \chi_0^{v\lambda} \rangle}{E_r - E_0 - h\nu - ib\Gamma_r} + \frac{\langle \chi_0^{v\lambda} | \langle \varphi_0 | \hat{\mu}_j | \varphi_r \rangle \langle \varphi_r | \hat{\mu}_i | \varphi_0 \rangle | \chi_0^{v\lambda} \rangle}{E_r - E_0 - h\nu - ib\Gamma_r} \right] \\ &= \langle \chi_0^{v'\lambda} | \alpha_{ij}(\mathcal{Q}\lambda) | \chi_0^{v\lambda} \rangle \end{aligned} \quad [14]$$

using eqn [2]. The result thus involves the dependence of the electronic polarizability on the nuclear coordinate $\mathcal{Q}_\lambda$ relating to the excited vibration. Although all molecules

have a finite polarizability, that is not the case for $\alpha_{ij}^{v'_i v'_j}$ – but no Raman signal will emerge when the latter is zero. Here a powerful symmetry rule emerges: any Raman-active vibration must transform under an irreducible representation spanned by components of the polarizability tensor (transforming as the quadratic variables x^2 , xy , etc., or one of their combinations). Some of the broad implications of this are highlighted below.

To obtain the major selection rules for Raman scattering we can first expand eqn [14] in a Taylor series about the equilibrium configuration Q_e ;

$$\alpha_{ij}(Q_\lambda) = \alpha_{ij}(Q_e) + \left. \frac{\partial \alpha_{ij}}{\partial Q_\lambda} \right|_{Q_e} (Q_\lambda - Q_e) + \dots \quad [15]$$

and hence we have

$$\alpha_{ij}^{v'_i v'_j} = \alpha_{ij}(Q_e) \delta_{v'v} + \left. \frac{\partial \alpha_{ij}}{\partial Q_\lambda} \right|_{Q_e} \langle \chi_0^{v'_i} | (Q_\lambda - Q_e) | \chi_0^{v'_j} \rangle + \dots \quad [16]$$

The first term on the right is non-zero only when the initial and final states are identical – which relates back to Rayleigh scattering. It is the second term which is significant for the Raman process and its detailed form establishes two rules governing Raman-allowed transitions, since both of its factors must then be non-zero. For the Dirac bracket to be non-zero dictates $v' = v \pm 1$, as in infrared absorption spectroscopy. For the polarizability derivative to be non-zero, the polarizability must change during the vibration, as the molecule passes through its equilibrium configuration. This is the key selection rule for the Raman effect, illustrated for CO_2 in **Figure 4**.

It is immediately apparent that Raman transitions are governed by different selection rules from absorption or fluorescence. The case of CO_2 illustrates a general principle applicable to all centrosymmetric molecules, which is that only gerade vibrations (those which are even with respect to inversion symmetry) appear in the Raman spectrum, whilst only ungerade vibrations (odd

with respect to inversion) show up in infrared absorption. This illustrates the so-called mutual exclusion rule for centrosymmetric molecules, which states that vibrations active in the infrared spectrum are inactive in the Raman, and vice versa. Even for complex polyatomic molecules lacking much symmetry, the intensities of lines resulting from the same vibrational transition may be very different in the two types of spectrum, so that in general there is a useful complementarity between the two methods. Generally it is the vibrations of the most polarizable groups which are strongest in the Raman spectrum, those of the most polar groups being strongest in the infrared, as nicely illustrated in the spectra of the drug acetaminophen (UK paracetamol; *p*-hydroxyacetanilide) shown in **Figure 5**.

Further information on the symmetry properties of Raman-active molecular vibrations can be obtained by measurement of the depolarization ratios of the lines in the Raman spectrum – see **Figure 3** and eqn [4]. Interpretation of the results here invokes eqn [17]:

$$\rho_I = \frac{3\gamma'^2}{4\gamma'^2 + 45\bar{\alpha}'^2} \quad [17]$$

The prime on the mean and anisotropy parameters, $\bar{\alpha}'$ and γ' , respectively, denote values obtained from the polarizability derivative – defined in the sense of eqn [5], but in components of the tensor $\partial\alpha_{ij}/\partial Q_\lambda$ rather than α_{ij} itself. In the case of gases and liquids, ρ_I is lower than $\frac{3}{4}$ for vibrations that are totally symmetric (vibrations transforming under the totally symmetric representation of the molecular point group), but exactly $\frac{3}{4}$ for other vibrations that lower the molecular symmetry, since $\bar{\alpha}'$ is then zero.

Although the frequency of radiation used for the study of Raman scattering is generally well removed from any absorption band of the sample, to forestall problems associated with absorption and subsequent fluorescence, special features become apparent on irradiation at a frequency close to a broad and intense optical absorption band. Quite simply, the closer the approach, the greater is the intensity of the Raman spectrum. Spectra obtained under such conditions are known as resonance Raman spectra. In the case of large polyatomic molecules where any electronic absorption band may be due to localized absorption in a particular chromophore, the vibrational Raman lines which experience the greatest amplification are those of the appropriate symmetry involving vibrations of nuclei close to the groups responsible for the resonance.

Equation [13] correctly represents the Raman tensor even under resonance or pre-resonance conditions – and the resonance enhancement is clearly attributable to the fact that if there is an excited state for which $E_r^{v'_\mu} - E_0^{v'_\mu}$ is close to $h\nu$, the first term of that equation has a denominator of greatly diminished magnitude. However, the

Figure 4 Variation of polarizability in the course of three normal modes of vibration of carbon dioxide: (a) symmetric stretch, (b) bending mode and (c) antisymmetric stretch. The slope $\partial\alpha/\partial Q_\lambda$ on crossing the vertical axis is non-zero only for the symmetric stretch, and hence only this vibration gives a Raman signal.

Figure 5 Fourier-transform spectra of paracetamol: (a) Raman, and (b) infrared. Stretch vibrations of the non-polar C–H groups, close to 3000 cm^{-1} , show up well in the Raman spectrum. In the infrared spectrum this whole region is dominated by stretching vibrations of the highly polar O–H and N–H groups, much broadened through association with hydrogen bonding. Reproduced with permission of Nicolet Instruments.

subsequent development of theory leading to eqn [16] is no longer valid under such conditions; for example, the $\nu' = \nu \pm 1$ selection rule breaks down and overtones commonly appear. Other vibrations (those which transform like the rotations R_x , R_y and R_z) can also become active through changed selection rules, associated with the fact that the Raman tensor is no longer real and index-symmetric, but complex and non-symmetric. As a result the equations for the Raman depolarization ratio

also require modification to the following form

$$\rho_i^{\text{res}} = \frac{3\gamma'^2 + 5\delta'^2}{4\gamma'^2 + 45\bar{\alpha}'^2} \quad [18]$$

where

$$\delta'^2 = \frac{1}{4} \sum_{i=x,y,z} \sum_{j=x,y,z} |\alpha'_{ij} - \alpha'_{ji}|^2 \quad [19]$$

is a measure of the degree of antisymmetry in the Raman tensor. One consequence of including this factor in eqn [18] is the possibility of depolarization ratios exceeding the normal upper bound of $\frac{3}{4}$ – in some cases indeed yielding an infinite result (complete depolarization).

Generally, the use of circularly polarized light in studies of Rayleigh or Raman scattering offers no further information beyond that provided by plane polarizations. However, optically active (chiral) compounds in the liquid or solution state respond differentially to circularly polarized light, according to its handedness, making it possible to obtain a spectrum showing a marginal difference in the Raman intensity $I^R - I^L$ as a function of scattering frequency. The extent of this differential for each molecular vibration is directly related to the detailed stereochemical structure responsible for the manifestation of chirality. In particular, the extent of differential scattering in a region of the spectrum associated with a particular group frequency can be interpreted in terms of the chiral environment of the corresponding functional group. In contrast to the theory developed here, the scattering entails not only electric dipole but also the much weaker magnetic dipole and electric quadrupole interactions.

At the high intensities now available from laser sources, numerous other variants of the Raman effect can be observed, many associated with optically nonlinear behaviour. For analytical purposes the most important of these come under the heading of coherent Raman spectroscopy, of which the process known as CARS (coherent anti-Stokes Raman spectroscopy) is the most common.

Here, two beams are directed into the sample: one has a fixed frequency playing the role of ν and the other, a frequency ν' tunable across the Stokes range. As ν' tunes into each Stokes frequency ν_S a four-photon process occurs, essentially combining all the elements of **Figure 1a** and **Figure 1b**, and generating coherent emission at the corresponding anti-Stokes frequency ν_{AS} . The laser-like nature of this output facilitates its collection for spectroscopic analysis, and permits the analysis of microscopic samples.

Reflectance Methods and Applications

Introduction

The amount of light reflected or scattered by a solid or particulate medium changes with wavelength. These spectral variations are caused by wavelength-dependent absorption and not only give rise to the sensation of color, but can also be used to infer such properties of the material as composition, complex refractive index, and electronic or molecular structure. The relative amount of light scattered into different directions depends on the physical structure, such as particle size and spacing, of the material. Both the spectral and directional variations of the reflectance can be measured without physically contacting the medium, and hence, they form a major tool in the study of planetary surfaces by remote sensing. Virtually all spacecraft that fly by or orbit the earth or other planets carry imaging spectrometer array detectors for this purpose.

Absorption spectra are commonly measured by transmittance, for which a thin slab of material is sliced off and both sides polished. One advantage of measuring spectra by diffuse reflectance is convenience: the only preparation required is that the sample be in powder form. Another is that if the absorbance is too strong, it may be difficult to prepare and handle a section thin enough to pass light through, whereas the powder can simply be ground to a finer size. On the negative side, the process of diffuse reflectance involves multiple scattering of photons from one particle to another and is highly nonlinear. Thus, fairly complex reflectance models are required to extract quantitative spectral absorption coefficients.

As with gases, absorption by solids usually occurs in discrete bands, the exception being metals, which absorb over a broad range of wavelengths. However, most solid state bands are much broader than their gaseous counterparts, with $\Delta\lambda/\lambda \sim 10\%$ being typical, where λ is the wavelength. For this reason the bands often overlap, complicating their recognition and sometimes producing an apparent absorption continuum.

Solid state bands arise from a variety of causes. Absorption in metals and semiconductors is due to photon-induced motion of conduction band electrons, which then collide with impurities or irregularities and transfer this energy to the solid state lattice. In insulators, ultraviolet, visible, and near-infrared photons are absorbed by electronic transitions, while at mid-infrared and radio frequencies absorption occurs by changes in the vibrational and rotational states of the ions of the lattice. The

electronic transitions are of three types: valence to conduction band jumps, electronic excitation, in which an electron remains localized on one ion while changing its orbital state, and charge transfer, in which its localization state moves from one ion to another nearby.

Specular Reflection: Kramers-Kronig Spectroscopy

If the medium is continuous and homogeneous and is separated from a vacuum by a smooth plane interface, light incident on the surface will be reflected in a specular or mirror-like manner, and the amount reflected is governed by the Fresnel reflection coefficients. For vertically incident light of arbitrary polarization, the specular reflectivity of the intensity is

$$r_s(\nu) = \frac{(n_r - 1)^2 + n_i^2}{(n_r + 1)^2 + n_i^2} \quad [1]$$

corresponding to the reflection coefficient for the amplitude of the electric field,

$$\frac{E_{\text{reflected}}}{E_{\text{incident}}} = \frac{1 - n_r - in_i}{1 + n_r + in_i} \quad [2]$$

where $n(\nu) = n_r(\nu) + in_i(\nu)$ is the complex index of refraction, ν is the frequency, and $i = \sqrt{-1}$.

If $n_i^2 \ll 1$, n_r can be calculated from a measurement of $r_s(\nu)$ directly using eqn [1]. If the imaginary component is not negligible, both components of n can still be obtained from $r_s(\nu)$ using the Kramers-Kronig method. The reflection coefficient can be written in the form

$$E_{\text{reflected}}/E_{\text{incident}} = \eta \exp(i\phi) \quad [3]$$

where $\eta(\nu) = \sqrt{r(\nu)}$ and $\tan\phi(\nu) = 2n_i/[(n_r^2 - 1 + n_i^2)]$. Solving for the components of n ,

$$n_r = \frac{1 - \eta^2}{1 - 2\eta \cos \phi + \eta^2}, \quad n_i = \frac{2\eta \sin \phi}{1 - 2\eta \cos \phi + \eta^2} \quad [4]$$

Assuming that n is analytic, the quantities η and ϕ must satisfy the Cauchy relations:

$$\phi(\nu) = -\frac{2\nu}{\pi} \int_0^\infty \frac{\ln[\eta(\nu')]}{\nu'^2 - \nu^2} d\nu', \quad \ln[\eta(\nu)] = \frac{2}{\pi} \int_0^\infty \frac{\nu' \phi(\nu')}{\nu'^2 - \nu^2} d\nu' \quad [5]$$

The reflectivity r_s is measured over as wide a range of wavelengths as possible, from which $\eta = \sqrt{r_s}$ is found.

A suitable theory, such as the Drude or Lorentz model, is used to extrapolate the measured data to zero and infinity, and the result inserted into eqn [5] for ϕ ; then n_r and n_i as functions of frequency or wavelength are found from eqns [4].

Diffuse Reflectance from a Particulate Medium

The reflectances of disordered particulate media, such as powders in the laboratory, soils, or planetary regoliths, are problems of particular theoretical and practical interest. Most reflectance measurements are one of two types: bidirectional reflectance, denoted by r_{bd} , in which the surface is illuminated from one direction by highly collimated light, such as sunlight or a laser, and is observed by a detector that subtends a small angle as seen from the surface; and directional-hemispherical reflectance, denoted by r_b , in which the surface is illuminated by collimated light, but the total light scattered into all directions is integrated and measured using an integrating sphere. The latter type of reflectance is also known as the hemispherical reflectance, hemispherical albedo, and plane albedo. Other types of reflectance, including hemispherical-directional and bihemispherical, are also possible. In planetary photometry the total fraction of incident sunlight scattered into all directions by a solar system object is called the Bond albedo, and is equal to the bihemispherical reflectance.

The most elementary bidirectional reflectance is an empirical expression known as Lambert's law,

$$r_L(i, e, g) = \frac{1}{\pi} \cos i \quad [6]$$

where i is the angle between the direction to the source of illumination and the normal to the sample surface, e is the angle between the direction to the detector and the normal, and g is the phase angle, the angle between the directions to the source and detector subtended at the surface. This equation is widely used because of its simplicity. Although no material is known to obey Lambert's Law exactly, several purified powdered forms of high albedo materials, such as titanium dioxide, barium sulfate, and polytetrafluoroethylene, come close. Thus, these materials can provide a convenient empirical reflectance standard. For mechanical reasons many reflectance spectrometers cannot measure the incident irradiance J directly. Instead, the measured radiance I of light scattered by the material of interest is ratioed to the radiance scattered at $i=e=0$ by the standard, which is assumed to be a Lambert surface. A quantity F is defined as $F=J/\pi$ and the ratio of reflectances is called the radiance factor, denoted by I/F .

At present the exact solution of Maxwell's equations for scattering by a plane electromagnetic wave incident on a disordered semi-infinite medium of interacting particles can be found numerically only for systems of a few particles of simple shapes. Hence, approximate methods and models must be used. The most widely used of these models assume that the powder can be treated as a continuous medium containing embedded scattering and absorption centers in which plane waves or photons diffuse through it in a manner that can be described by a form of the Boltzmann transport equation known as the equation of radiative transfer.

Let a particulate medium be illuminated from above by collimated light of irradiance J from a distant source of electromagnetic radiation. The surface of the medium is the $z=0$ plane and is examined by a distant detector located in the empty space above the surface. Let the radiance within and above the surface be $I(z, \Omega)$, where Ω is the direction of propagation. Then the equation of radiative transfer is

$$\cos \vartheta \frac{\partial I(z, \Omega)}{\partial z} = -EI(z, \Omega) + \frac{1}{4\pi} \int_{\Omega=4\pi} I(z, \Omega') G(\Omega', \Omega) d\Omega' + J \frac{1}{4\pi} G(\Omega_0, \Omega) \exp\left(-\frac{Ez}{\cos i}\right) \quad [7]$$

where ϑ is the angle between Ω and the positive z axis, Ω_0 is the direction of the incident irradiance, i , E is the extinction coefficient, and $G(\Omega', \Omega)$ is the average probability of light being scattered by an element of the medium from direction Ω' to direction Ω . The first term on the right-hand side of eqn [7] gives the decrease of I caused by scattering and absorption as the wave propagates through the medium, the second term describes the increase of I due to light traveling in direction Ω' scattered into direction Ω , and the third term is the source term and describes how I is increased as incident irradiance is scattered from direction Ω_0 into direction Ω .

Define the scattering coefficient S , single scattering phase function $p(\theta)$, and single scattering albedo w by $G(\Omega', \Omega) = Sp(\theta)$, where θ is the angle between Ω' and Ω , and $p(\theta)$ is normalized so that

$$\frac{1}{2} \int_0^\pi p(\theta) \sin \theta d\theta = 1 \quad [8]$$

and $w=S/E$; w is the fraction of light scattered by an average scattering element of the medium. For a particulate medium of identical particles

$$E = N\sigma Q_E$$

$$S = N\sigma Q_S$$

and

$$w = Q_S/Q_E \quad [9]$$

where N is the number of particles per unit volume, σ is their rotationally averaged cross-sectional area, Q_E is the extinction efficiency (which includes both scattering and absorption), and Q_S is the scattering efficiency. If the particles are large compared with the wavelength, the scattering elements of the medium can be identified with the individual particles so that w is the fraction of light scattered by a particle. If the particles are smaller than the wavelength, the nature of the scattering element is rather nebulous, but is probably defined by the clumps and statistical irregularities in the packing of the particles.

With these definitions, eqn [7] can be put into the form

$$-\cos\theta \frac{\partial I(z, \Omega)}{\partial \tau} = -I(z, \Omega) + \frac{w}{4\pi} \int_{\Omega=4\pi} I(z, \Omega') p(\theta) d\Omega' + J \frac{w}{4\pi} p(\theta_0) \exp\left(-\frac{\tau}{\cos i}\right) \quad [10]$$

where θ_0 is the angle between Ω_0 and Ω , and τ is the optical depth:

$$\tau = \int_z^\infty E dz' \quad [11]$$

No exact analytic solutions to eqn [10] in closed form have been obtained. However, because this equation is important in theories of stellar and planetary atmospheres, including the earth's, it has been studied extensively and numerical solutions tabulated for many cases of interest. The simplest case is that of isotropically scattering particles, $p(\theta)=1$, for which the radiance emerging from the surface in the direction toward the detector is given by

$$I(i, e, g) = J \frac{w}{4\pi} \frac{\mu_0}{\mu_0 + \mu} H(w, \mu_0) H(w, \mu) \quad [12]$$

where $\mu = \cos e$, $\mu_0 = \cos i$, and $H(w, x)$ are the Ambartsumian-Chandrasekhar H-functions given by the solutions to the integral equation

$$H(w, x) = 1 + \frac{w}{2} x H(w, x) \int_0^1 \frac{H(w, x')}{x + x'} dx' \quad [13]$$

These functions are tabulated in many references. An approximate expression for them, accurate to better than 3%, is

$$H(w, x) \approx \frac{1 + 2x}{1 + 2x\sqrt{1-w}} \quad [14]$$

If the particles of the medium do not scatter isotropically, but are not too anisotropic, a useful approximate solution

for the bidirectional reflectance is

$$r_{bd}(i, e, g) = \frac{I(i, e, g)}{J} = \frac{w}{4\pi} \frac{\mu_0}{\mu_0 + \mu} [p(g) + H(w, \mu_0) H(w, \mu) - 1] \quad [15]$$

where $H(w, x)$ is given by eqn [14], and $g = \pi - \theta$ is the phase angle.

The directional-hemispherical reflectance for isotropic particles is

$$r_b = \frac{1}{J\mu_0} \int_0^{\pi/2} I(i, e, g) \cos e \sin e de = 1 - \sqrt{1-w} H(w, \mu_0) \quad [16]$$

To predict the reflectance of a medium by forward modeling of solutions to the radiative transfer equation, w and $p(g)$ must be specified. If the particles are spheres these quantities may be calculated from the size and refractive index using Lorenz-Mie theory. If the particles are not spherical, but are not too irregular, T-matrix theory can be used. However, the particles in most regoliths and laboratory powders are much larger than the wavelength, are irregular in shape, and may have reentrant surfaces; often they are filled with internal scatterers, such as impurities, voids, and crystalline boundaries. The only method by which the scattering parameters of such particles can be calculated exactly is the Monte Carlo ray tracing technique, which is too unwieldy and CPU-intensive to be practical for most applications. An approximate semi-empirical model for w is the equivalent slab model in which the single scattering albedo is given by

$$w = S_e + (1 - S_e) \frac{(1 - S_i)\Theta}{1 - S_i\Theta} \quad [17]$$

where S_e is the integral of the Fresnel reflection coefficients for light externally incident uniformly from all directions on a plane surface of a material with the same refractive index as the particle and S_i is similarly defined for light incident from within the material, Θ is the internal transmission factor

$$\Theta = \frac{r_i + \exp(-\sqrt{\alpha(\alpha+s)}D)}{1 + r_i \exp(-\sqrt{\alpha(\alpha+s)}D)} \quad [18]$$

Here D is a length of the order of the mean particle size, α is the absorption coefficient,

$$\alpha = 4\pi n_i/\lambda \quad [19]$$

s is the internal scattering coefficient, and r_i is the internal scattering factor

$$r_i = \frac{1 - \sqrt{\alpha/(\alpha+s)}}{1 + \sqrt{\alpha/(\alpha+s)}} \quad [20]$$

If there are no internal scatterers, $s=0$, $r_i=0$, and $\Theta = \exp(-\alpha D)$. Approximate expressions for the surface reflection coefficients are

$$S_e = 0.0514 + 0.9183r_s, \quad S_i = 1 - \frac{4}{n_r(n_r + 1)^2} \quad [21]$$

where r_s is the specular reflectivity eqn [1].

Equation [17] takes into account the two major processes that are involved in the scattering of light by a particle: surface scattering, which is Fresnel reflection from the outer surface, and volume scattering, which is light that has been refracted into the particle and scattered back out by either the internal scatterers or internal reflection from the surface. The first term on the right-hand side of eqn [17] is the surface scattering; the second term describes the volume scattering, including all orders of reflection from surfaces and internal scatterers.

An empirical approximate expression for the single scattering albedo is

$$w = \frac{1}{1 + \alpha D_e} \quad [22]$$

where D_e is an effective particle diameter of the order of the mean particle size, but which also depends on the internal scattering coefficients. This expression is less accurate than eqn [17] and is valid only for $\alpha D < \sim 2$.

An isolated particle larger than the wavelength of light is a highly anisotropic scatterer because $p(g)$ has a strong, narrow, Fraunhofer diffraction peak in the forward direction at $g=180^\circ$ caused by portions of wavefronts that pass by the particle interfering positively with each other. This peak is part of w and $p(g)$ when they are calculated using Lorenz-Mie or T-matrix methods. However, when the same particle is part of a close-packed medium, the surrounding particles block this light, so that the diffraction peak does not exist and must be removed from such calculations. Thus, $p(g)$ is much less anisotropic when in a powder than when in a sparsely packed medium, such as an aerosol, and may often be described to a sufficient approximation by the first few terms of a series of Legendre polynomials

$$p(g) = 1 + \sum_{j=1}^{\infty} b_j P_j(\cos g) \quad [23]$$

where $P_j(\cos g)$ is the Legendre polynomial of order j . Since particle-scattering functions typically have both forward and backward scattering lobes, terms up to at least second order are required for a realistic description.

Another widely used representation of $p(g)$ is the double-lobed Henyey-Greenstein function:

$$p(g) = \frac{1+c}{2} \frac{1-b_1^2}{(1-2b_1 \cos g + b_1^2)^{3/2}} + \frac{1-c}{2} \frac{1-b_2^2}{(1+2b_2 \cos g + b_2^2)^{3/2}} \quad [24]$$

where $0 \leq b_1, b_2 \leq 1$, and c can have any value. Frequently it is sufficient to set $b_1 = b_2$. The only other restriction on the b and c parameters is that $p(g) \geq 0$.

Reflectance Spectroscopy

Spectra obtained by reflectance have a large number of uses, such as verification of solid state molecular orbital calculations by comparison with measurements and determination of composition by comparison of remotely measured spectra with libraries of known composition. If the composition of a particulate medium is known the particle size can be estimated, since the band depths and shapes depend on size.

Figure 1 shows a typical bidirectional reflectance in which this quantity is plotted against phase angle. The dots show the measured values of a powder consisting of spherical glass particles of known size and refractive index. The line is the reflectance predicted from eqn [15], in which w and $p(g)$ were calculated using Lorenz-Mie theory but with the diffraction peak removed. The overall agreement is quite satisfactory.

The reflectance, whether bidirectional or hemispherical, is determined mainly by the single scattering albedo, which controls the height of the reflectance and the angular shape of the bidirectional reflectance. The single scattering phase function essentially fine-tunes them. Figure 2 plots the bidirectional and hemispherical

Figure 1 Bidirectional reflectance (radiance factor I/F) for a powder of glass spheres with $n = 1.51 + i3.5 \times 10^{-5}$ and diameters between 2 and 50 μm , with the source fixed at $i = 60^\circ$. The detector was varied between 70° on either side of the normal in the vertical plane containing the source and the surface normal. The dots are the measured data and the line is predicted from eqn [15].

reflectances, eqns [14]–[16], for a medium of isotropically scattering particles versus w . The figures show that the reflectances are nonlinear functions that increase monotonically with w .

To extract quantitative absorption spectra from measurements of the reflectance spectra of powders it is necessary to first determine w by reverse modeling of solutions to the radiative transfer equation, such as eqn [15]. Ideally, the bidirectional reflectance is measured over as wide a range of phase angles as possible and w and $p(g)$ are found by linear regression analysis. However, $p(g)$ cannot be determined from the hemispherical reflectance alone, and often the bidirectional reflectance is measured at only a single set of angles. In these cases the only way to proceed is to assume that the scattering is isotropic ($p(g) = 1$) and solve for w .

The dependence of the single scattering albedo, eqn [17], on absorption coefficient is shown in Figure 3, in which w is plotted versus αD . When $\alpha D \ll 1$, $w \approx 1$, and the reflectance is high. As αD increases, w and the reflectance decrease. When $\alpha D > \sim 5$ the second term in eqn [17] becomes negligible and w bottoms out at $w = S_e$. In this region, the reflectance is insensitive to α . As n_i and α increase still further to the point where n_i^2 is no longer $\ll 1$, S_e and w increases in accordance with eqn [21]. This illustrates a seemingly paradoxical property of absorption bands seen in reflectance: relatively weak bands ($\alpha D < \sim 5$) give rise to reflectance minima, but strong bands ($n_i^2 > \sim 0.1$) cause reflectance maxima.

Figure 3 also plots the approximate expression for w , eqn [22]. To retrieve quantitative spectra of $\alpha(\lambda)$ from $w(\lambda)$, the parameters in eqn [17] must be specified.

Figure 2 The bidirectional reflectance radiance factor (I/F) at $i=0$, $e=5^\circ$, and $g=5^\circ$ calculated from eqn [15], and the directional-hemispherical reflectance r_h at $i=0$ from eqn [15].

Sometimes these are known or can be estimated from other information about the material, but often they are completely unknown. In this case a relative absorbance spectrum $\alpha(\lambda)D_e$ can be obtained using eqn [22] for w , keeping in mind that this expression is valid only in the region of w where αD_e is small. If α is independently known at one or a few wavelengths, this can be used to calibrate D_e by fitting the spectrum at those wavelengths.

Figure 4 compares the spectrum of the absorption coefficient of a silicate glass doped with Ca^{2+} measured from the transmittance of a thin section and retrieved from the diffuse reflectance of the glass in powder form. The approximate eqn [22] for w was used with D_e adjusted to match the transmission data in the blue region of the spectrum. The agreement is excellent except at the highest values of α , where eqn [22] begins to lose accuracy.

Mixtures

Most particulate media encountered in nature or the laboratory are mixtures of different types of particles. The particles may differ in terms of size, shape, composition, degree of surface roughness, and internal structure. There are two types of mixtures: linear or checkerboard, and nonlinear or intimate. Linear mixtures occur when different types of deposits are side-by-side within the field of view of the detector, such as a field of soil next to a snow pack. In that case the reflectance is simply the average of the individual reflectances weighted by area.

In a nonlinear mixture, the different types of particles are together in intimate contact. Because multiple

Figure 3 Single scattering albedo versus αD . Solid line is eqn [17]; in this example $n_r = 1.50$, $4\pi D/\lambda = 5$, and $s = 0$. Dashed line is the approximate expression [22] in which $D_e = 2.595 D$.

Figure 4 Comparison of the spectral absorption coefficient of a cobalt silicate glass measured by transmission of a thin section (solid line) and by reflectance of the glass in powder form (open circles). Reproduced from Hapke B and Wells E (1981) Bidirectional reflectance spectroscopy. 2. Experiments and observations. *Journal of Geophysical Research* 86: 3055–3060, with permission from the American Geophysical Union.

scattering is a nonlinear process the reflectances do not combine linearly. Mixtures may be taken into account by generalizing eqns [9]. Denote the various types of particles by subscript j . Then eqns [8] become

$$E = \sum_j N_j \sigma_j Q_{Ej}, \quad S = \sum_j N_j \sigma_j Q_{Sj}$$

and

$$w = \left(\sum_j N_j \sigma_j Q_{Sj} \right) / \left(\sum_j N_j \sigma_j Q_{Ej} \right) \quad [25]$$

If the particles are roughly spherical, the bulk density of the j th type of particle is

$$B_j = \rho_j N_j \pi D_j^3 / 6 \quad [26]$$

where ρ_j is the solid density of the j th type of particle, and D_j is their diameter. When the particles are much larger

than the wavelength, $Q_{Ej} \approx 1$ to a sufficient approximation, and w becomes

$$\begin{aligned} w &= \left(\sum_j \frac{B_j \frac{\pi D_j^2}{4} Q_{Sj}}{\rho_j \frac{\pi D_j^3}{6}} \right) / \left(\sum_j \frac{B_j \frac{\pi D_j^2}{4} Q_{Ej}}{\rho_j \frac{\pi D_j^3}{6}} \right) \\ &= \left(\sum_j \frac{B_j}{\rho_j D_j} w_j \right) / \left(\sum_j \frac{B_j}{\rho_j D_j} \right) \end{aligned} \quad [27]$$

where $w_j = Q_{Sj} / Q_{Ej}$. Equation [27] is the mixing formula for intimate mixtures and may be inserted into the appropriate equations to calculate the reflectance.

The Raman effect is an inelastic light scattering process where the incoming laser radiation with angular frequency ω_0 is modified by changes of the scattering system, which either reduce or enlarge the energy of the radiation. These two components of the inelastically scattered light are called Stokes and anti-Stokes signals, with angular frequencies $\omega_S = \omega_0 - \omega_R$ and $\omega_{AS} = \omega_0 + \omega_R$, respectively. Here, the article focuses on vibrational Raman spectroscopy of molecules, and ω_R therefore denotes the angular frequency of the corresponding molecular vibration.

Figure 1(a) shows the energy scheme of the Stokes process in normal Raman scattering, for which the energy

$\hbar\omega_0$ of the incident radiation is much smaller than the energy $\hbar\omega_{ri}$ required for an electronic transition in the molecule. Preresonance Raman scattering, schematically shown in **Figure 1(b)**, is observed when the excitation frequency ω_0 approaches the transition frequency ω_{ri} . When both frequencies are nearly equal, as in **Figure 1(c)**, discrete resonance Raman scattering (RRS) occurs. In addition to the fundamental transition, several overtones due to transitions from vibrational levels in the electronic excited state to different vibrational levels of the electronic ground state may also be observed. When the excitation energy is large enough to reach the dissociative levels of the molecular system, as shown in **Figure 1(d)**, continuum RRS is observed.

Selectivity and sensitivity are two unique advantages of RRS over normal Raman scattering. The selectivity in RRS arises from the fact that only signal contributions of normal modes associated with the corresponding electronic transition are enhanced. Signal intensities in RRS are typically several orders of magnitude higher compared to normal Raman scattering. This increase in sensitivity will be explained in the following section on theoretical aspects of RRS.

Figure 1 Classification of different vibrational Raman scattering processes. ω_0 is the frequency of the exciting laser, ω_{ri} denotes the frequency associated with the transition from the electronic ground state (i) to an excited electronic state (r) of the molecule. Theoretical Description of Raman and Resonance Raman Scattering

The incoming laser field is described by an electromagnetic wave with an electric field vector that oscillates with angular frequency ω_0 :

$$\vec{E} = \vec{E}_0 \cos \omega_0 t \quad [1]$$

This oscillating electric field induces a dipole in the molecule:

$$\vec{\mu} = \alpha \vec{E} \quad [2]$$

where α is the polarizability tensor that determines the probability of the Raman transition $i \rightarrow f$. Equation [2] can also be written as a system of linear equations using Cartesian coordinates:

$$\begin{bmatrix} \mu_x \\ \mu_y \\ \mu_z \end{bmatrix} = \begin{bmatrix} \alpha_{xx} & \alpha_{xy} & \alpha_{xz} \\ \alpha_{yx} & \alpha_{yy} & \alpha_{yz} \\ \alpha_{zx} & \alpha_{zy} & \alpha_{zz} \end{bmatrix} \cdot \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} \quad [3]$$

The Raman polarizability tensor can be correlated with the Raman scattering cross-section. Calculating the total intensity I_{fi} of scattered photons per molecule per second for a transition from $i \rightarrow f$ yields

$$I_{fi} = CI_0 \omega_{sc}^4 \sum_{\rho, \sigma} |(\alpha_{\rho\sigma})_{fi}|^2 \quad [4]$$

with

- I_0 : intensity of the incident photons with angular frequency ω_0
- ω_{sc} : angular frequency of the scattered light
- C : constant that depends on the unit system used
- ρ, σ : indices denoting fixed coordinates.

The quantum mechanical derivation of the polarizability tensor components $(\alpha_{\rho\sigma})_{fi}$ is known as the Kramers–Heisenberg–Dirac (KHD) dispersion relation:

$$(\alpha_{\rho\sigma})_{fi} = \sum_r \left[\frac{\langle f | \mu_\rho | r \rangle \langle r | \mu_\sigma | i \rangle}{\hbar \omega_{ri} - \hbar \omega_0 - i \Gamma_r} + \frac{\langle f | \mu_\sigma | r \rangle \langle r | \mu_\rho | i \rangle}{\hbar \omega_{rf} + \hbar \omega_0 - i \Gamma_r} \right] \quad [5]$$

with

- ω_{ri} : angular frequency associated with a transition from initial state i of the Raman transition to any state r of the unperturbed molecule
- Γ_r : damping factor related to the lifetime of the state r
- $\langle f | \mu_\rho | r \rangle$: ρ th component of the transition dipole moment associated with a transition from any state r of the unperturbed molecule to the final state f of the Raman transition
- μ_ρ : dipole moment operator in the direction of ρ .

The first term in eqn [5] begins to dominate when the angular frequency ω_0 of the exciting light approaches the transition angular frequency ω_{ri} for an absorption band of the molecule and the resonantly excited state then dominates the sum over states of the Raman polarizability expression. Thus, for excitation into an absorption band of the molecule with $\omega_0 \approx \omega_{ri}$ as shown in Figure 1(c), eqn [5] may be written as follows:

$$(\alpha_{\rho\sigma})_{fi} = \sum_r \left[\frac{\langle f | \mu_\rho | r \rangle \langle r | \mu_\sigma | i \rangle}{\hbar \omega_{ri} - \hbar \omega_0 - i \Gamma_r} \right] \quad [6]$$

Within the Born–Oppenheimer approximation, the eigenstates $|i\rangle$, $|f\rangle$, and $|r\rangle$ of the unperturbed molecule may be expressed as products of electronic, vibrational, and rotational states. Confining the discussion to the vibrational RR effect, that is, assuming that the molecule is initially in the vibrational state $|v_i\rangle$ and that the Raman transition starts and terminates in the electronic ground state $|g\rangle$, the corresponding wavefunction may be written as follows

$$|i\rangle = |g v_i\rangle = |g\rangle |v_i\rangle$$

and

$$\begin{aligned} |f\rangle &= |g v_f\rangle = |g\rangle |v_f\rangle \\ |r\rangle &= |e v_e\rangle = |e\rangle |v_e\rangle \end{aligned} \quad [7]$$

where $|e\rangle$ represents the resonantly excited electronic state, whereas $|v_f\rangle$ and $|v_e\rangle$ correspond to the final vibrational state of the Raman process and the vibrational state in the excited electronic state, respectively.

Using eqn [7], the dipole transition moment in the numerator of eqn [6] becomes

$$\begin{aligned} \langle f | \mu_\rho | r \rangle &= \langle v_f | M_\rho^e | v_e \rangle \\ \langle r | \mu_\sigma | i \rangle &= \langle v_e | M_\sigma^e | v_i \rangle. \end{aligned} \quad [8]$$

M^e is the pure electronic transition moment connecting the ground state i with the excited state e , whereas v_i , v_f , and v_e are the vibrational wavefunctions. The dependency of M^e on the nuclear coordinates can be written as a Taylor series around the equilibrium position (Herzberg–Teller expansion):

$$M^e = M_0^e + \left(\frac{\partial M^e}{\partial Q} \right)_0 Q + \dots \quad [9]$$

Similar expressions are valid for each of the 3N–6 (3N–5) normal coordinates in a nonlinear (linear) molecule. Inserting eqns [8] and [9], into eqn [6] yields

$$(\alpha_{\rho\sigma})_{fi} = A + B + \dots \quad [10]$$

where

$$A = \sum_{e,v_e} \frac{M_{0\rho}^e M_{0\sigma}^e}{\hbar\omega_{ri} - \hbar\omega_0 - i\Gamma_{ev}} \langle v_f | v_e \rangle \langle v_e | v_i \rangle$$

and

$$B = \sum_{e,v_e} \frac{M_{0\rho}^e \left(\frac{\partial M_{0\sigma}^e}{\partial Q} \right)_0}{\hbar\omega_{ri} - \hbar\omega_0 - i\Gamma_{ev}} \langle v_f | v_e \rangle \langle v_e | Q | v_i \rangle \\ + \sum_{e,v_e} \frac{\left(\frac{\partial M_{0\rho}^e}{\partial Q} \right)_0 M_{0\sigma}^e}{\hbar\omega_{ri} - \hbar\omega_0 - i\Gamma_{ev}} \langle v_f | Q | v_e \rangle \langle v_e | v_i \rangle$$

A and B are the so-called Albrecht A - and B -terms. The electronic transition moment M^e is generally much larger than $\left(\frac{\partial M^e}{\partial Q} \right)$, i.e. its derivative with respect to the normal coordinate. Thus, the A -term has dominant contributions to the RR intensity if the product of the Franck–Condon factors $\langle v_f | v_e \rangle$ and $\langle v_e | v_i \rangle$ does not vanish. However, the product $\langle v_f | v_e \rangle \langle v_e | v_i \rangle$ vanishes, when the vibration along Q is not totally symmetric, but is antisymmetric with respect to a symmetry element, making A -term equal to zero. This shows that only totally symmetric vibrations give rise to resonance enhancement via the A -term.

The displacement of the potential energy surface of the excited electronic state relative to the electronic ground state, as shown in **Figure 2**, is a further criterion

relevant to RR scattering via the A -term. In the case where there is no displacement of the geometry in the excited electronic state from that in the electronic ground state ($\Delta = 0$ in **Figure 2(a)**), the product of the two Franck–Condon factors vanishes and hence the RR intensity is zero. However, for $\Delta \neq 0$ in **Figure 2(b)**, all Franck–Condon factors are nonzero for both upward and downward transitions.

The enhancement via the B -term derives from the non-Condon dependence of the electronic transition moment on the vibrational coordinate and, unlike the A -term, arises from the vibronic mixing of two excited states. The active vibrations may have any symmetry that is contained in the corresponding direct product. In general, the enhancement via the B -term is significantly smaller than that via the A -term and can be clearly distinguished from it by excitation far away from the resonance. The B -term contribution to the transition polarizability may lead to an asymmetric ($\alpha_{\sigma\rho} \neq \alpha_{\rho\sigma}$) or antisymmetric ($\alpha_{\sigma\rho} = -\alpha_{\rho\sigma}$) scattering tensor, giving rise to the phenomenon of anomalous polarization. This will be shown in the following text for RRS on cytochrome c.

The time-independent description of RRS introduced earlier is based on the KHD dispersion relation (eqn [5]). The time-dependent formulation of RRS can be obtained through a straightforward mathematical transformation. Examples for calculating RR spectra by both approaches, KHD and the time-dependent picture, will be shown in the following text for iodine.

Advantages of RRS and Applications in Molecular Vibrational Spectroscopy

Advantages of RRS over conventional, electronically nonresonant RS include

1. *Sensitivity*: The enhanced Raman signal allows the use of dilute samples
2. *Selectivity*: Only the chromophoric unit within the entire molecule is probed
3. *Symmetry*: Probing the symmetry of the polarizability tensor by polarized experiments
4. *Vibronic Coupling*: Information on the coupling of nuclear and electronic coordinates.

Advances in laser technology provide the experimentalist with a variety of powerful light sources ranging from the far UV to the (mid-infrared) far and beyond. Nearly every chromophore can therefore be probed by RRS, and this technique has been applied to a broad range of molecular systems. Three representative examples of RRS in molecular vibrational spectroscopy (Table 1) are discussed here. Example 1 covers work on halogens, in particular iodine as an example for diatomic molecules, and illustrates the theoretical concepts discussed earlier. Porphyrins as biologically relevant coordination compounds were selected as Example 2 to demonstrate the potential of RRS in conjunction with polarization-resolved measurements to provide information on structure and symmetry. Example 3 on peptides and proteins has also considerable biological relevance: investigating protein structure as well as dynamics with far UVRRS is of great current interest. By using far UV excitation, protein-folding studies are possible via the selective enhancement of the polypeptide backbone.

Applications of RRS to Diatomic Molecules: Halogens

RRS has been extensively used for the investigation of diatomic molecules, in particular halogens. Kiefer and Bernstein, for example, investigated the fine structure in the overtone progression for iodine (I_2), using 488 nm excitation with an argon ion laser. About 15 overtones in the gas phase spectrum of I_2 and about the same number of overtones for I_2 dissolved in various organic

solvents were observed upon continuum excitation (see Figure 1(d)). The analysis of the overtone progression pattern allows the determination of anharmonicity constants x_e , and y_e from the experimentally observed vibrational wave numbers $\tilde{\nu}$:

$$\tilde{\nu}(v) = v\omega_e - (v^2 + v)\omega_e x_e + (v^3 + 3/2v^2 + 3/4v)\omega_e y_e + \dots \quad [11]$$

where v is the vibrational quantum number and ω_e is the harmonic frequency.

The explanation for the observation of the overtone series within the time-dependent picture of continuum RR scattering for this diatomic molecule is shown in Figure 3(a). The propagating wave packet $|i(t)\rangle$ in the excited electronic state evolves on a femtosecond time-scale. During this time, because of the high overlap of vibrational wavefunctions, iodine can be de-excited from the Π state to various vibrational levels of the electronic ground state X. The transitions for the second overtone with $\Delta v = 3$ are shown in Figure 3(b) and can be interpreted in terms of Q ($\Delta J = 0$) and S ($\Delta J = +2$) branches, J being the rotational quantum number.

In addition to the determination of the anharmonicity constants from the overtone progression, the excited-state potential function of diatomic molecules in the gas phase can also be determined. Continuum RR spectra of gaseous molecules also are very sensitive to the position and shape of the potential function involved and the electronic transition moments between ground and excited states. The simulation of continuum RR spectra of the fundamentals and overtones, by either the KHD or the time-dependent approach, allows a precise determination of the shape and position of the excited-state potential function. The procedure developed for diatomic molecules can be extended to polyatomic molecules to determine their excited-state geometry. Currently, time-dependent density functional theory (TDDFT) enjoys popularity in quantum chemistry as it allows efficient calculations of excited electronic states in larger molecular systems.

Applications of RRS to Metalloporphyrins: Hemes

RR spectroscopy has been extensively used for probing the structure and dynamics of metalloporphyrins. In this class of cyclic tetrapyrroles containing a N -coordinated metal center, the pyrrole rings are connected at the α -carbons via methine bridges and form a macrocycle as shown in Figure 4(a). The substituents at the β - (R_1 to R_8) and meso-positions of the macrocycle as well as the metal center and its oxidation state define a specific metalloporphyrin. A planar and undistorted

metalloporphyrin macrocycle has D_{4h} symmetry. Various parameters such as the substitution pattern, conjugation to side chains, axial ligands, and others may lower the degree of local symmetry; this can be probed by RRS, in particular when combined with a polarization-resolved detection.

Hemes are a prominent class of metalloporphyrins with iron (Fe) as the central atom. Heme proteins contain at least one heme moiety as a prosthetic group and the iron center has important functions such as oxygen transport in hemoglobin, electron transfer in cytochromes, and catalysis in heme enzymes. A comprehensive interpretation of the vibrational bands in the RRS spectra of metalloporphyrins requires normal coordinate calculations combined with group theory. Metalloporphyrins contain 37 atoms, when all peripheral substituents and axial ligands are neglected, which results in $105 = 3 \times 37 - 6$ normal modes; these vibrational modes can be further separated into 71 in plane and 34 modes, which transform as follows:

$$\begin{aligned}\Gamma_{\text{in plane}} &= 9 A_{1g} + 8 A_{2g} + 9 B_{1g} + 9 B_{2g} + 18 E_u \\ \Gamma_{\text{out of plane}} &= 3 A_{1u} + 6 A_{2u} + 4 B_{1u} + 5 B_{2u} + 8 E_g\end{aligned}\quad [12]$$

A and B indicate one-dimensional irreducible representations in contrast to the two-dimensional E symmetry species (each E_u or E_g entry represents a degenerate pair of modes). The D_{4h} character table together with the symmetry of the polarizability tensor helps in identifying Raman-active normal modes. Gerade modes such as the

totally symmetric A_{1g} modes, for example, are symmetric with respect to the center of inversion and Raman-active because they lead to a change in polarizability.

The corresponding absorption spectra are useful for the interpretation of RR spectra since the signal enhancement in RRS involves excited electronic states. For D_{4h} symmetric hemes, the absorption spectrum in **Figure 4(b)** shows the very intense B or Soret band at ~ 410 nm and the weaker Q bands, Q_0 and Q_1 , between 500 and 600 nm. Gouterman's four orbital model, involving the frontier molecular orbitals depicted in the inset in **Figure 4(b)**, give an explanation for the appearance of these absorption bands. Considering D_{4h} symmetry of the tetrapyrrole ring, the lowest unoccupied π^* orbitals are degenerate and have e_g symmetry, whereas the two highest occupied π orbitals have a_{1u} and a_{2u} symmetry, respectively. Since the lowest unoccupied molecular orbital (LUMOs) have nearly the same energy, there is a large interaction between the two excitations $a_{1u} \rightarrow e_g$ and $a_{2u} \rightarrow e_g$: the two transition dipoles can add up, leading to the intense B transition, or almost cancel each other, giving rise to the weaker Q_0 transition. Since Q and B transitions both have E_u symmetry, some intensity for the Q transition is regained via vibronic mixing with the B transition, leading to the Q_v sideband, which is an envelope of vibrational bands built on the Q_0 band. The allowed symmetry of mixing vibrations is given by the direct product of the two transitions with E_u symmetry:

$$E_u \times E_u = A_{1g} + A_{2g} + B_{1g} + B_{2g} \quad [13]$$

Figure 4 (a) Molecular structure of metalloporphyrins; (b) absorption spectrum of Fe(II) cytochrome c. The inset shows a schematic representation of Gouterman's four orbital model. Adapted from Spiro TG (1985) In: Anfinsen Jr CB, Edsall JT, and Richards FM (eds.) *Advances in Protein Chemistry*, vol. 37, p. 111. Orlando, FL: Academic Press.

To apply these symmetry aspects for the analysis of RR spectra, it is taken into account that the electronic transitions that give rise to the *B*- and *Q*-band are localized in the plane of the metalloporphyrin ring. As discussed earlier (eqn [12]) for D_{4h} symmetry, only the in-plane modes are RR-active. For excitation wavelengths close to the intense Soret band in **Figure 4(b)**, the corresponding RR spectrum in **Figure 5(a)**, upper part, is dominated mainly by totally symmetric (A_{1g}) modes of the tetrapyrrole macrocycle between 1300 and 1700 cm^{-1} . The strong intensity of these bands is due to the high oscillator strength of the Soret transition (M^e in eqn [10]). In contrast, the excited-state displacements, the second important factor for *A*-term scattering (via the Franck-Condon factors in eqn [10]), are relatively small for the C–N and C–C stretching vibrations due to the large size of the porphyrin macrocycle. For RR spectra with excitation close to the weak Q_0 and Q_1 bands in **Figure 4(b)**, totally symmetric modes are not dominantly enhanced as shown in **Figure 5(a)**, lower part, because *A*-term scattering varies with oscillator strength, which is an order of magnitude smaller for the Q_0 band than for the Soret band. Instead, nontotally symmetric modes are strongly enhanced due to *B*-term scattering because of the strong vibronic mixing of the Q_0 and Soret transition (see eqn [13]), which gives rise to the Q_1 band (**Figure 4(b)**).

The RR bands due to modes with different symmetry can be distinguished on the basis of their depolarization ratio ρ , determined experimentally from measurements of the parallel $I_{||}$ and perpendicular $I_{\perp}$ intensity

components (eqn [14]):

$$\rho = \frac{I_{\perp}}{I_{||}} = \frac{3\gamma_s^2 + 5\gamma_{as}^2}{45\bar{\alpha}^2 + 4\gamma_s^2}, \quad [14]$$

where $\bar{\alpha}$ is the mean polarizability, while γ_s and γ_{as} are the symmetric and antisymmetric part of the anisotropy, respectively:

$$\begin{aligned} \bar{\alpha} &= \frac{1}{3} \sum_{\rho\rho} \alpha_{\rho\rho} \\ \gamma_s^2 &= \frac{1}{2} \sum_{\rho\sigma} (\alpha_{\rho\rho} - \alpha_{\sigma\sigma})^2 + \frac{3}{4} \sum_{\rho\sigma} (\alpha_{\rho\sigma} + \alpha_{\sigma\rho})^2 \\ \gamma_{as}^2 &= \frac{3}{4} \sum_{\rho\sigma} (\alpha_{\rho\sigma} - \alpha_{\sigma\rho})^2 \end{aligned} \quad [15]$$

Considering the elements of the polarizability tensor and using eqn [15], the depolarization ratio for each mode can be calculated. For B_{2g} modes, the only nonzero component is α_{xy} , hence $\bar{\alpha}$ and γ_{as} are zero, yielding $\rho = 3/4$; the same results for B_{1g} modes, for which all off-diagonal elements of the polarizability tensor including α_{zz} are zero and $\alpha_{xx} = -\alpha_{yy}$, thus $\bar{\alpha}$ and γ_{as} are zero, yielding $\rho = 3/4$. In contrast to B_{1g} and B_{2g} modes, the totally symmetric A_{1g} modes are polarized ($\rho < 3/4$), since the diagonal elements of the tensor and therefore $\bar{\alpha}$ are nonzero, whereas γ_{as} is zero:

$$\rho = \frac{3\gamma_s^2}{45\bar{\alpha}^2 + 4\gamma_s^2} < \frac{3}{4} \quad [16]$$

Figure 5 (a) Raman spectra of Fe(II) cytochrome c obtained with 413 and 514 nm excitation; Siebert F and Hildebrandt P (2008) *Vibrational Spectroscopy in Life Science*, p. 230. Weinheim: Wiley-VCH; (b) polarized Raman spectra of Fe(II) cytochrome c obtained with 514 nm excitation; ip = inversely polarized, dp = depolarized, p = polarized. Adapted from Spiro TG (1985) In: Anfinsen Jr CB, Edsall JT, and Richards FM (eds.) *Advances in Protein Chemistry*, vol. 37, p. 111. Academic Press.

A_{2g} modes exhibit anomalous polarization ($\rho > 3/4$) because of the antisymmetric character of the polarizability tensor with $\alpha_{xy} = -\alpha_{yx}$. The anomalous polarization of the A_{2g} modes can be clearly seen in the polarized Raman spectra of Fe(II) cytochrome c in **Figure 5(b)**; for these inversely polarized (ip) modes, the perpendicular intensity $I_{\perp}$ is larger than the parallel component $I_{\parallel}$.

Applications of RRS to Biopolymers: Peptides and Proteins

Proteins are biopolymers containing amino acids as monomers, which are connected by planar amide units. The conformation of a peptide backbone is determined by the so-called Ramachandran angles ψ and ϕ shown in **Figure 6** (top). Vibrational spectroscopy provides a label-free approach to protein structure determination because the wavenumber positions of the bands from the peptide backbone are sensitive to secondary structure elements such as α -helix and β -sheet. These structure-sensitive vibrations of the peptide bond give rise to the amide A, amide B, and amide I–VII bands, which can be selectively enhanced with far UV excitation. The eigenvectors for the in-plane modes amide I to amide III are shown in **Figure 6** (bottom).

The amide I band mainly originates from the peptide C=O stretching vibration with small contributions from N–H in-plane bending. The amide I band appears at $\sim 1650 \text{ cm}^{-1}$ and its wavenumber position depends on the secondary structure. The amide II mode comprises C–N in-plane stretching and N–H deformation components, and it usually occurs as a weak band at $\sim 1560 \text{ cm}^{-1}$. The amide III band, originating mainly from N–H in-plane bending, appears at $\sim 1250 \text{ cm}^{-1}$ and is very sensitive to the conformation of the peptide backbone.

Figure 7 shows the selective enhancement of different vibrational bands in a heme protein by the choice of the excitation wavelength, using carbonmonoxy-hemoglobin (HbCO) as an example. The electronic absorption spectrum in **Figure 7(a)** shows the characteristic Soret or B band at $\sim 400 \text{ nm}$ due to the four heme units in HbCO as well as the absorption due to the peptide backbone in the far UV. The values of 197, 229, and 419 nm indicate the laser excitation wavelengths used for obtaining the corresponding RR spectra shown in **Figure 7(b)**. Excitation at 419 nm selectively probes the heme units in HbCO, whereas 229 nm excitation probes the aromatic amino acids tyrosine and tryptophan. At 197 nm excitation, Raman bands of phenylalanine and the amide backbone are selectively enhanced. Far UV laser excitation therefore provides a direct probe of

Figure 6 Peptide backbone structure (top) and eigenvectors of the amide I–III vibrations (bottom).

Figure 7 (a) Absorption spectrum and structure of HbCO; (b) Raman spectra of HbCO obtained with 197, 229, and 419 nm laser excitation, respectively. protein secondary structure and offers unique opportunities to also probe protein dynamics such as folding and unfolding.

The folding dynamics of a protein is very complex since different structural components appear at different timescales. Many approaches have been developed to probe protein-folding pathways, all of them providing different degrees of structural details on different timescales. Nanosecond time-resolved UVRR spectroscopy, for example, has also been applied to investigate the earliest events in protein structure formation as it

combines high temporal with high spectral resolution. Fast kinetic studies of protein folding can be performed by initiating protein unfolding via a laser-induced temperature jump (T -jump) and probing transient species by Far UV Raman spectroscopy. Asher and coworkers investigated the thermal unfolding of the 21 amino acid α -helical peptide $A_5[AAARA]_3A$ (AP). **Figure 8** (lower part) depicts the static far UVRR spectra of AP at 4, 30, and 70 °C obtained with 204 nm excitation. At high temperatures, the spectra are dominated by amide I (1655 cm^{-1}), amide II (1547 cm^{-1}), C_α -H bending

Figure 8 Temperature-dependent static UVRRS spectra of AP at 4, 30, and 70 °C obtained with 204 nm excitation (bottom); transient difference UVRRS spectra after the T -jump from 4 °C to ~ 37 °C at several nanosecond delay times; the static UVRRS spectrum of AP at 4 °C has been subtracted from each transient spectrum (top). Adapted from Lednev IK, Karnoup AS, Sparrow MC, and Asher SA (1999) Nanosecond UV Resonance Raman Examination of Initial Steps in α -Helix Secondary Structure Evolution. *Journal of the American Chemical Society* 121: 4076, with permission from Elsevier.

(1382 cm^{-1}), and amide III (1244 cm^{-1}) bands. **Figure 8** (upper part) also shows the transient UVRR difference spectra of AP measured after the T -jump from 4 °C to ~ 37 °C at several nanosecond delay times; these difference signatures only reflect spectral changes occurring due to the T -jump because the static UVRR spectrum at 4 °C has been subtracted as a reference. The static UVRR difference spectrum of AP samples between 37 °C and 4 °C (**Figure 8**, top) shows peaks, which result from the melting of AP α -helices to random coil peptides. At the shortest delay times, a small feature, which results from the known downshifts of the amide II and amide III bands with temperature, can be observed. The random coil formation is observed at longer delay times. The temperature-dependent UVRR measurements indicate the existence of an equilibrium between α -helices and random coil. The α -helix content decreases with increasing

temperature and is converted into random coil at high temperature.

Thus, far UVRR studies with nanosecond time resolution contribute to a mechanistic understanding of protein folding and unfolding. A further dissemination of this powerful time-resolved vibrational spectroscopic technique is prognosed for biophysical as well as other applications where both high time and structural information can be acquired without the need of perturbing external labels.

In summary, applications of RRS in this contribution, which range from diatomics such as iodine to proteins as representatives for large polyatomic biomolecules, are discussed. The references listed in the Further Reading section may serve as a guide to the original literature.

Introduction

The function of many rigid solids is tied to their structure and hence there are questions in the study of synthetic, natural and biomaterials that can be addressed by imaging methods. In fact, the first nuclear magnetic resonance (NMR) images of rigid solids were acquired by Peter Mansfield and co-workers in 1973, the same year that Paul Lauterbur introduced the field of NMR imaging. NMR imaging of liquids rapidly advanced to where very sophisticated methods are used for clinically important diagnosis in medicine along with related techniques for the study of microscopy and complex flow dynamics. Progress in the study of rigid solids by NMR imaging has been somewhat slower, due partially to the priorities given to health care issues, but also due to technical challenges introduced by the broad NMR resonance lines of rigid solids. From a spectroscopy point of view the difference between a liquid and rigid solid is tied to the orientational dependence of NMR parameters such as chemical shifts and dipolar couplings. Mobile liquids have sufficient rotational motion that orientational dependencies are averaged to their isotropic value (hence the dipolar interaction vanishes since it has no isotropic component). For imaging purposes the sharper line widths seen in liquids lead to higher spatial resolution with simple imaging methods; however, the tensor properties of the full interactions permit more interesting forms of contrast to be achieved for solids. The goal then in NMR imaging of solids has been to develop methods that provide high quality images in the presence of broad lines and which can also take advantage of the greater array of contrast mechanisms. These methods fall into two

general classes, Wide-line methods that achieve spatial resolution by overwhelming the broad resonance line with a stronger magnetic field gradient, and coherent averaging approaches that carry out the imaging experiment in an interaction frame where the line width is reduced.

Coherent and Incoherent Imaging

The basic ideas of NMR imaging are frequently presented as a simple result of the following three concepts:

1. the NMR resonance frequency is directly proportional to the applied magnetic field strength,
2. the NMR signal intensity is directly proportional to the spin concentration,
3. time-dependent linear magnetic field gradients can be applied along any arbitrary direction.

The simple idea is that a spatially varying magnetic field encodes the positions of the spins in their resonance frequencies, and thus the number of spins at any given location may be directly measured as the intensity of the NMR signal at the corresponding resonance frequency.

This real space picture of imaging corresponds best to an incoherent measurement where each spatial location is interrogated sequentially and the full image of the sample is built up from a sequence of such measurements. In such an approach the relative NMR signals from two different spatial locations have no phase (or coherent) relationship to one another. Incoherent imaging methods are occasionally employed in solid-state imaging with the stray field imaging (STRAFI) method being the best known example (see below).

Most solid-state imaging (and virtually all modern liquid-state imaging) is carried out as coherent measurements where a specific phase relation is established between the signal from spins at different locations. It is this phase that is modulated throughout the course of the measurement. Such approaches have the advantage that the entire sample is measured simultaneously, leading to a multiplexing gain in the sensitivity. Coherent imaging is best introduced in a space reciprocal to real space, and discussed in terms of magnetization gratings.

Magnetic Field Gradients, Gratings, and k -Space

The presence of a spatially varying magnetic field across the sample results in spins at different locations precessing at different rates, and so after some time they rotate to be out of phase with each other. This establishes a relative phase shift that depends on the difference in the magnetic fields that the spins see and the evolution time. In most imaging, the spatially varying field is arranged to be a linear magnetic field gradient so that the difference in fields is directly proportional to the separation of the spins, with the proportionality constant being the strength of the magnetic field gradient (an experimentally controlled parameter).

Differential spin precession sets up a magnetization grating across the sample corresponding to a linear ramp of the phase of the nuclear spin (see **Figure 1**). Grating pictures of the spin dynamics emphasise the coherent nature of the imaging experiment, making it clear that there is a phase relation between any two given spins. The magnetization grating is most conveniently

characterized by its corresponding wavenumber, k , which is,

$$k = 2\pi/\lambda \quad [1]$$

where λ is the spatial period of the grating – identified in **Figure 1**.

As the spins evolve in the magnetic field gradient, they are wound up into progressively tighter spirals and the pitch of the spiral continuously decreases, corresponding to an increasing wavenumber. In a constant magnetic field gradient the wavenumber increases linearly with time,

$$k(t) = k(0) + \gamma \partial B_z / \partial Z t \quad [2]$$

For simplicity the gradient has been written as though it varies along the z -axis, in practice this could be any direction, and γ is the gyromagnetic ratio.

The key relationship between the grating and the imaging measurement is that the NMR signal is the spin magnetization integrated over the sample. The grating thus is a spatial modulation of the spin density, $\rho(x, y, z)$,

Figure 1 A schematic representation of a one-dimensional imaging measurement and the corresponding magnetization grating. Notice that the pitch of the spatial helix becomes finer over time resulting in measurements of progressively higher wavenumbers, or Fourier components of the spin density. In a multidimensional imaging measurement wave vectors in 2 or 3 dimensions are independently modulated.

at a given spatial period. The signal as a function of the wavenumber, $s(k)$, is a Fourier component of the local spin density of the sample,

$$s(k) = \int \rho(r) \exp(k \cdot r) dr \quad [3]$$

where k is the reciprocal variable of the real space laboratory frame and r is a vector in 3D space.

In a coherent picture then the imaging experiment reduces to a series of measurements as a function of the wavenumber in three-dimensional space and taking the inverse Fourier transform of the NMR signal returns the real space image. At this level of approximation, the field of view and spatial resolution are given directly by the Nyquist sampling theorem.

There are a wealth of schemes for how to efficiently sample k -space in two or three dimensions. Since these are not unique to solid state studies the reader is referred to the descriptions in MRI theory.

The Complications from Rigid Solids

The picture set up above is complete when the gradients are the sole source of spin evolution, there is no relaxation and the spins do not move. In the liquid state the gradients can often be made sufficiently strong that relaxation and chemical shifts are minor complications and the limits to resolution and image distortions arise from limited NMR sensitivity and molecular transport. For rigid solids, molecular transport is not an issue, but the short lifetime of the transverse spin magnetization is.

The transverse relaxation time of proton-rich, rigid solids can be as short as tens of microseconds resulting in only this very limited time to impose a grating across the sample and to measure a given Fourier component. As seen from eqn [2] a given wavenumber (and hence spatial resolution) can still be reached, but as the lifetime of the transverse spin magnetization decreases the gradient strength must correspondingly increase. To obtain a wavenumber of $2\pi/20 \mu\text{m}$ in $10 \mu\text{s}$ a gradient of 1000 G cm^{-1} is needed. Typical gradients for small samples are of the order of 100 G cm^{-1} although gradients as strong as $100\,000 \text{ G cm}^{-1}$ have been employed in NMR.

The gradient strength is only a technical issue and large gradients are certainly available; their use in imaging, however, is limited by a corresponding loss in sensitivity. NMR is a very insensitive spectroscopy, with the most significant noise source being white noise from the receiver coil. As the gradient strength is increased the effective frequency bandwidth of the smallest volume element (voxel) also increases and the noise increases as the square root of the frequency spreads (or gradient strength). Thus, as the resolution is made finer, and the

voxel shrinks, the signal decreases with the number of spins in the voxel and the noise increases with the gradient strength. The overall result is that wide-line methods that rely upon large gradients to overwhelm the broad NMR line width typically have low resolution and low signal-to-noise ratios.

Formally, since the gradient evolution and the natural evolution of the spin system (that due to chemical shifts and dipolar couplings, etc.) commute with each other, the NMR spectrum blurs the image as a convolution. Of course the spectrum is in frequency units, and the image is in spatial units, so one must convert between these, and the gradient strength provides the necessary scaling,

$$\text{image}(x, y, z) = \rho(x, y, z) \otimes \text{spectrum} \left(\frac{2\pi\nu}{\gamma(\partial B_z / \partial z)} \right) \quad [4]$$

The comparison between liquid and solid-state imaging is shown schematically in Figure 2.

Methods

While obtaining an image is relatively straightforward and can be accomplished with methods that are closely related to those successfully employed in liquid state studies, the broad line width of rigid solids will result in low resolution and sensitivity unless special care is taken. This can be accomplished in three ways,

1. wide-line methods can be employed but with multiple sampling to increase the limited sensitivity,
2. constant-time methods can be used that accept the loss in sensitivity, but recover resolution by using the fact that the gradient and internal Hamiltonians commute,

Figure 2 A comparison of a series of 1D images as a function of the NMR line width with a constant gradient. The NMR line width is varied from 0.1% to 100% of the separation between the two bands in the image. As the resolution degrades so also does the sensitivity. Coherent averaging recovers both by artificially narrowing the NMR resonance. The solid state and coherent averaging line widths can differ by a factor of 10^4 .

3. finally, the broad line width does not need to be accepted; it can be refocused through the use of coherent averaging resulting in a simultaneous increase in both resolution and sensitivity.

Wide-Line/Strong Gradients

Wide-line methods accept the limitation to resolution imposed by the sample's line width and use strong gradients to achieve high spatial encoding. The most successful of these is stray field imaging (STRAFI) where the sample is rotated and translated through the strong magnetic field gradient that is found at the fringe of any superconducting solenoid magnet. The imaging process is incoherent since only a single sensitive slice of the sample is observed at any given time, and the reconstruction process is based on the filtered back projection algorithm. The STRAFI method is described in detail in the article on MRI using stray fields.

Although the STRAFI method gives up the sensitivity advantage from the multiplexing inherent in coherent imaging approaches, a smaller multiplexing advantage can be achieved since there is no need to wait for spin lattice relaxation between the measurement from one slice to the next. In addition, the gradient-imposed noise bandwidth of coherent imaging can be partially avoided through pulsed spin-locked detection, essentially a narrow-band excitation and filtering that locally has good sensitivity.

STRAFI, like most wide-line methods, is typically free of distortions that can plague coherent averaging-based imaging methods, but may introduce its own artifacts if the mechanics for sample motion are not excellent. In addition, the method is inherently three-dimensional and so the imaging time is very long.

A challenge of stray field (and wide-line methods) is that the types of contrast that can be introduced are rather limited, and usually based on rotating frame relaxation times. Contrast arising from the commonly observed spectroscopic parameters, particularly the chemical shift, cannot be achieved.

Constant-Time Methods

As pointed out above, the gradient evolution and that from internal interactions commute at high fields, and so these act independently on the spin system. Emid and Creyghton pointed out that since these commute and since the gradient interaction is under experimental control, it is possible to set up the k -space sampling in such a fashion that the data are taken at a constant time following the excitation pulse (see **Figure 3**). The internal interactions lead to their normal complex spin evolution, but this is identical from measurement to measurement and therefore can be removed from the convolution: the only thing that changes is the gradient;

Figure 3 The pulse sequence and k -vectors for constant-time imaging. Notice that all of the data are collected at a constant time following the excitation pulse and yet the k -vector is still modulated from point-to-point by systematically varying the strength of the gradient.

eqn [4] may thus be rewritten as,

$$\text{image}(x, y, z) = \text{fid}(t_s) \rho(x, y, z) \quad [5]$$

where the value of the normalized free induction decay at the sampling time, $\text{fid}(t_s)$, is a complex number with magnitude less than unity. Notice that since the sampling time is kept constant, the free induction decay is not transformed into a spectrum by the inverse Fourier transform.

In constant-time methods the line width of the NMR resonance no longer blurs the image and the image resolution is solely determined by the sampling conditions for the coverage of k -space. The line width does, however, limit the sensitivity, and so constant-time methods make the normal trade-off of sensitivity for resolution. At the same time, however, they achieve a robust experimental setup that is easy to apply.

With the typical 100 G cm^{-1} gradients available from commercial small scale liquid-state imaging equipment, constant-time methods can be used to observe rigid solids, but at very low S/N ratios and at low spatial resolution.

Constant-time methods are also used in liquid-state imaging and in NMR microscopy to avoid distortions from chemical shifts and local variations in the bulk magnetic susceptibility.

Coherent Averaging

One of the most significant advances in the development of high resolution NMR methods for solids is Waugh's demonstration that the complex spin evolution in strongly coupled rigid solids can be refocused. This result is most easily understood in an interaction frame picture that depends on the time independence of the dipolar Hamiltonian in a rigid solid, rather than focusing on the complex spin dynamics. The interaction frame Hamiltonian can be periodically modulated through mechanical rotation (to modulate the geometric dependence), or through a series of RF pulses (to modulate the spin dependence), and in such a fashion that the time-averaged value is zero. Provided that the NMR response is sampled within this frame then the interaction appears to vanish. Coherent in this case corresponds to the structure of the modulation that is responsible for line-narrowing, and not a spatial phase as in the imaging case. Coherent averaging differentiates the steady experimentally controlled, driven modulation from a natural stochastic, incoherent process.

For imaging, coherent averaging means that we are not left to suffer the blurring from the broad resonance of a typical solid, but we can 'artificially' narrow this to achieve both higher sensitivity and resolution. Indeed, the first solid state images that were acquired by Mansfield and co-workers in 1973 used coherent averaging precisely for this purpose. Coherent-averaging methods have been developed to average dipolar couplings, chemical shifts, susceptibility shifts, and all of these simultaneously.

Coherent averaging for imaging has taken four approaches:

- Magic angle sample spinning (MAS) – which has the advantage of permitting contrast based on the isotropic chemical shift. MAS by itself, however, rarely removes the dipolar broadening efficiently.
- Multiple-pulse sequences based on solid echoes – which are very efficient at refocusing all internal interactions and can be combined with pulsed gradients to avoid image distortions.
- Multiple-pulse sequences based on magic echoes – which are very similar to the solid echo-based methods, but have the advantage of longer windows for the gradients.
- Multiple-pulse sequences based on off-resonance excitation – where the effective interaction frame rotates at the magic angle and dipolar interactions can be

made to vanish. Imaging in this interaction frame requires a combination of matched RF and d.c. gradients.

MAS is conceptually the simplest of these. Andrew demonstrated that a pair of dipolarly coupled spins are effectively decoupled from one another if the sample is spun at the 'magic-angle', the [111] direction – or the bisector of a cube. This rotation effectively removes the dipolar broadening from the system, and has the advantage of also removing the anisotropic chemical shift while leaving the isotropic shift for contrast generation. The challenge, of course, is that as the sample is rotating the imaging experiment must keep up with the sample and a variety of means have been engineered to synchronize the imaging experiment to the frame of reference rotating with the sample (see **Figure 4**). Once in this frame, the imaging methods are very similar to liquid state methods and the solid state aspects can, for the most part, be ignored.

Unfortunately, MAS alone, even at 20 kHz rotation rates, does not produce narrowing of the line width of a dipolarly coupled rigid solid. The challenge here is that the state of the nuclear spins are modulated by energy conserving mutual flip/flops (one spin flips to up while a neighbour flops to down) at a correlation time that is much faster than the modulation frequencies reached through sample rotation. So, MAS works well in special cases but in general must be combined with a multiple-pulse method.

Multiple-pulse methods achieve line narrowing by modulating the spin states quickly and symmetrically (see **Figure 5**). The promise of multiple-pulse approaches to solid-state imaging is both high resolution and good sensitivity, and that these can be combined with great flexibility in terms of contrast and image geometry. The challenge for multiple-pulse imaging is that the gradient evolution no longer commutes with the internal Hamiltonians as they are modulated, and so the spin dynamics of the gradient and internal Hamiltonians are no longer independent of each other. This can lead to pronounced image distortions, where the residual NMR line width depends on the gradient-induced frequency shift. The cleanest way to avoid such distortions is to apply the gradient in selected, symmetry-related windows, which, however, requires specialized hardware to deliver strong fast gradient pulses.

Multiple-pulse imaging permits a surprisingly wide range of image contrast even though the internal Hamiltonian is suppressed during the imaging sequence. This, of course, removes the possibility of building contrast into the image during data sampling, and so most solid-state imaging methods are preceded with a contrast-generating sequence and perhaps slice selection if a two-dimensional image is desired.

Figure 4 The experimental setup for MAS imaging. The sample rotates about the magic angle at a frequency of about 10 kHz, and the current through the gradient coils is modulated so that the gradient fields move with the sample. ν_m is the magic angle, 54.7° .

Figure 5 The pulse sequence for a representative multiple-pulse, coherent averaging imaging measurement. The series of RF pulses lead to a refocusing of the dipolar and chemical shift interactions over the full cycle, and the gradients are added in selected windows. Even though the gradient and internal Hamiltonians do not commute, by restricting the gradients to selected windows an image which is substantially free of distortions can be collected. By placing the gradient pulses between each dipolar decoupled π pulse a larger effective gradient is achieved, but at a cost of some distortions, these are avoided by placing the gradients more sparsely where the gradient RF interaction is avoided, to second order.

Figure 6 MAS image of the polybutadiene fraction of a poly-butadiene/polystyrene blend cast as a film from toluene. MAS alone at 5 kHz spinning is not sufficient to narrow the polystyrene NMR resonance. The in-plane resolution is $50 \times 50 \mu\text{m}^2$. Figure reproduced with permission from Cory DG, de Boer JC, and Veeman WS (1989) Magic angle spinning ^1H NMR imaging of poly-butadiene/polystyrene blends. *Macromolecules* 22: 1618.

Resolution and Field of View

Resolution in NMR imaging of solids is primarily limited by the low sensitivity of NMR. Typical detection limits are of the order of 10^{15} spins in the solid-state, so that minimum voxels are approximately $10^4 \mu\text{m}^3$ (or a cube $20 \mu\text{m}$ on edge). Along any one dimension the resolution can be somewhat higher, but the volume remains approximately constant. The various approaches to solid-state imaging present additional limitations to the resolution.

STRAFI methods rely on sample translation and so the precision and reproducibility of the mechanical arrangement also limits the resolution, here to approximately $10 \mu\text{m}$. STRAFI methods are also set up to provide isotropic voxels in 3D-imaging, although much work has been done with 1D-STRAFI measurements where the question has been carefully tailored so they can be answered by studying profiles of the sample.

Constant-time methods trade off significant sensitivity for resolution at a rate determined by the gradient strength. These methods typically work best for large objects where lower resolution is required and the gradient evolution time can be kept short.

Magic angle spinning-based imaging methods are very close to liquid state studies and the resolution limits normal in microscopy (better than $10 \mu\text{m}$) apply here; however, spinning speeds are not sufficient to study most rigid solids. For rigid materials multiple-pulse coherent averaging is preferred and here the limitation relates to the challenges of sampling in the presence of multiple-pulse and pulsed gradients. In practical terms this

Figure 7 (a) T_{2e} -magic-echo image of a piece of polycarbonate (see schematic) in which a crossed shearband has been created. (b) An image of a sample that has been stretched nearly to the breaking point: The regions with high intensity correspond to areas of low molecular mobility. Figure reproduced with permission from Traub B, Hafner S, Maring D, and Spiess HW (1998) In: Blümli P, Blümich B, Botto B, and Fukushima E (eds.) *Spatially Resolved Magnetic Resonance*. Weinheim: Wiley-VCH, p. 191.

permits about 128 volume elements to be acquired along a given axis and so the resolution is tied to the sample size.

This last point is more general, given sampling time and the lower efficiencies of larger detection coils imaging methods are typically limited to 512 elements along a side (or less). So the highest resolutions are achieved with small samples.

A related issue is the allowable size of the field of view. Solid-state imaging methods typically impose mechanical constraints on the sample size, such as to fit within the strong gradient in STRAFI (about 15 mm), or within the rotor for MAS methods (about 5 mm). Multiple-pulse methods work best in very high RF fields, and so the sample is limited to fitting within a relatively small RF coil (about 10 μm). Some single-sided imaging methods have been explored and are certainly feasible for soft materials, but are less well developed for rigid solids.

Availability of Instruments and Methods

NMR imaging of rigid solids is still mainly limited to experts who typically build a significant portion of their own equipment. Constant-time methods are the most widely available and can be used for preliminary studies, but the low sensitivity make many studies prohibitively long. STRAFI probes are commercially available, but here also the time to acquire an image is long and the

restricted means of generating contrast limits applications. Magic angle sample spinning probes with a single magnetic field gradient along the spinner axis have become commercially available (for NMR spectroscopic studies of semisolids) but probes with 3D gradient sets must still be homemade. All multiple-pulse coherent averaging approaches to imaging are carried out in homebuilt probes, and used with or without an associated fast gradient pulser. A large part of the challenge in employing multiple-pulse methods is the required stability and precision of the RF which typically demands the attention of an experienced spectroscopist to set up.

Applications

Most of the effort in NMR imaging of rigid solids has been directed towards developing robust, high quality imaging methods, and few applications have been investigated in any detail. However, there are now a variety of good methods and it is an appropriate time for applications.

Proposed applications include the study of structure and morphology in synthetic polymers, an example being the selective imaging of one component of a multi-component blend (see **Figure 6**). Such studies can be extended to the mapping of rigid versus mobile segments in a processed material (see **Figure 7**). There are a wealth of questions in materials processing and ageing

Figure 8 Three-dimensional constant-time image of a bovine femur showing both the compact bone and the interior bone marrow. The image resolution is $1.1 \times 1.1 \times 4.4 \text{ mm}^3$ and the image was acquired over a period of 5 h. Figure reproduced with permission from Balcon BJ (1998) In: Blümmler P, Blümich B, Botto B, and Fukushima E (eds.) *Spatially Resolved Magnetic Resonance*. Weinheim: Wiley-VCH, p. 84.

that can be investigated by such methods, even though the resolution of the image is on the order of tens of micrometres.

There has also been interest in biomedical studies of bone, bone cements and the function of synthetic organs. An example of an image of bovine bone is shown in **Figure 8**. Progress has also been made in developing methods of following bone repair *in vivo*.

Synopsis

The rotational spectra of gas phase molecules is explained using the quantum theory of angular momentum. The spectra of simple rigid molecules are explained on the basis of selection rules and energy level expressions which depend upon the moments of inertia of the molecules. We consider how the theory needs to be extended to include effects of nonrigidity, and also small effects due to interactions between the angular momentum of the nuclear framework, electron spins, and nuclear spins. A calculation of relative intensities using spherical tensor techniques is given for a diatomic molecule using Hund's case *a*.

Introduction

The rotational spectroscopy of molecules typically (but by no means always) occurs in the microwave region of

the spectrum. In solids, molecules are usually not free to rotate, and in liquids collisions normally render absorption featureless; we therefore consider only the rotational spectroscopy of gaseous molecules.

Spectroscopic assignments are often discussed in terms of selection rules which determine whether or not it is possible for a transition in a molecule to be caused by a particular interaction, such as the electric dipole interaction. The only true selection rules are for total angular momentum (F) and parity (+ or −). For complex molecules with many different angular momenta, it is more profitable to discuss spectra in terms of relative intensities rather than 'allowed transitions'. We can readily calculate the relative intensities for many types of transitions in different molecules using the quantum theory of angular momentum.

Rotational effects (fine structure) are also seen in high resolution electronic and vibrational spectra; additional structure due to the interaction of electrons with nuclear electric and magnetic moments may also be observed and is called hyperfine structure. The simplest rotational spectra are associated with diatomic molecules with no electronic orbital or spin angular momentum (i.e. singlet sigma states) and these are considered first.

The theory of rotational spectroscopy depends upon an understanding of the quantum mechanics of angular momentum. Useful results from the quantum theory of angular momentum are given in **Table 1** and useful results in spherical tensor notation are given in **Table 2**.

A full understanding of a rotational spectrum is achieved when we can calculate the rotational energy levels of the molecules and then calculate the frequencies and intensities of the transitions between them. The cheapness and availability of computers and subroutines for diagonalizing matrices means that most spectra are now assigned on the basis of calculated spectra iterating towards convergence with measured line positions and intensities; we discuss how this is accomplished.

Born–Oppenheimer Approximation

The Born–Oppenheimer approximation assumes that the molecular wavefunction can be written in the form $\psi_{\text{total}} = \psi_{\text{electronic}}\psi_{\text{vibration}}\psi_{\text{rotation}}$ and therefore that the energies due to each type of motion are additive E_{total}

Table 1 Useful results from the quantum theory of angular momentum

$$J^2|JKM\rangle = J(J+1)|JKM\rangle \hbar^2$$

$$J_z|JKM\rangle = K|JKM\rangle \hbar$$

$$J_y|JKM\rangle = M|JKM\rangle \hbar$$

$$J^\pm|JKM\rangle = (J_x \pm iJ_y)|JKM\rangle = [(J \mp M)(J \pm M + 1)]^{1/2}|JKM \pm 1\rangle \hbar$$

The lower result shows the operation of the shift (or ladder) operator in the space-fixed axis system using the normal phase convention. Angular momentum relationships are based on the commutation relationships

$$[J_x, J_y] = i\hbar J_z$$

$$[J^2, J_z] = 0$$

Addition of two angular momenta:

$$J = J_1 + J_2$$

and the allowed values of the quantum number J are given by

$$J = J_1 + J_2, J_1 + J_2 - 1, \dots, |J_1 - J_2| \quad [1]$$

Molecule fixed angular momenta are problematic, because the commutation relationships between different components are reversed. There are many ways of taking account of this, but the easiest is to calculate everything in space-fixed axes and convert (where necessary) to molecule fixed axes by using eqns [13] and [14].

$= E_{\text{electronic}} + E_{\text{vibrational}} + E_{\text{rotational}}$. This gives rise to electronic and vibrational quantum numbers which are often a good first order description of the energy levels and wavefunctions of a molecule. The application of the Born–Oppenheimer approximation leads naturally to the rigid rotor description of a molecule – we treat the rotation separately from the vibrational motion of the nuclei, which are considered later as a perturbation.

The rotational motion of a molecule is quantized in units of $\hbar$, and this free rotation can take place about three orthogonal axes which are associated with three distinct moments of inertia, I_A , I_B , I_C . The moments of inertia are, in fact, quantum mechanical expectation values of the moments of inertia in a particular electronic and vibrational state of the molecule. We associate the moments of inertia with three rotational constants, A , B , C , which determine the energy levels of the molecule.

The Hamiltonian for rotation is $H_r = A J_A^2 + B J_B^2 + C J_C^2$. If the molecule has symmetry then we can take advantage of the symmetry to rewrite the Hamiltonian in a form which is easy to solve. The appropriate Hamiltonians and energy level expressions are given in Table 3.

Molecules without Electronic or Nuclear Angular Momentum

The simplest spectra belong to molecules with no electronic angular momentum and no nuclear spin angular momenta and we consider these first. The relevant classifications, Hamiltonians and energy level expressions are given in Table 3. The quantum mechanical treatment of spherical motion gives rise to the eigenfunctions of the spherical top ψ_{rotation} which we denote by the ket

$|JKM\rangle$; the letters inside the brackET denote the quantum numbers used to describe the state. For other problems involving rotation it is convenient to use a basis of $|JKM\rangle$ states and express the eigenfunctions of each problem as a linear combination of them, that is:

$$|J\Gamma\rangle = \sum_K a'_K |JKM\rangle$$

$$H_{\text{rotation}}|J\Gamma\rangle = E|J\Gamma\rangle$$

For a molecule, there are two projection quantum numbers of $\mathbf{J}$ which are simultaneously conserved, M and K . M is the space-fixed projection of $\mathbf{J}$ and K is the molecule-fixed projection of $\mathbf{J}$. Both M and K can take values from $+J$ to $-J$ in steps of one. In the absence of an electric or magnetic field the eigenvalues are independent of M and each eigenfunction gives rise to an eigenvalue which is $2J+1$ degenerate.

Spherical Top Molecules

The spherical top has the same simple energy level pattern as a linear molecule. However, a spherical top cannot have a permanent dipole moment, and therefore has no rotational spectrum.

Linear Molecules (Including Diatomic Molecules)

The linear molecule energy levels are given by $E = B \cdot J(J+1)$, where J is the rotational quantum number for rotation perpendicular to the bond, and B is the rotational constant. The energy level structure is given in Figure 2 (left). A typical rotational spectrum (of a diatomic molecule) is shown in Figure 1.

Then the reduced matrix element of $X_p^k(\mathbf{A}, \mathbf{B})$ is related to those of $T^{k_1}(\mathbf{A})$ and $T^{k_2}(\mathbf{B})$ by the general expression

$$\langle \gamma J \| X^k(\mathbf{A}, \mathbf{B}) \| \gamma' J' \rangle = [2k+1]^{1/2} (-1)^{k+J+J'} \sum_{j''} \left\{ \begin{matrix} k_1 & k_2 & k \\ j' & j & j'' \end{matrix} \right\} \langle \gamma J \| T^{k_1}(\mathbf{A}) \| \gamma'' J'' \rangle \langle \gamma'' J'' \| T^{k_2}(\mathbf{B}) \| \gamma' J' \rangle \quad [7]$$

where $\left\{ \begin{matrix} k_1 & k_2 & k \\ j' & j & j'' \end{matrix} \right\}$ is a Wigner 6-j symbol.

The general formula can be simplified if the two operators commute, i.e. if $T^{k_1}(\mathbf{A})$ operates only on one part of a coupled system (J_1) and $T^{k_2}(\mathbf{B})$ on another (J_2) then the reduced matrix elements of $X_p^k(\mathbf{A}, \mathbf{B})$ are given by:

$$\langle \gamma J_1 J_2 J \| X^k(\mathbf{A}, \mathbf{B}) \| \gamma' J_1 J_2 J' \rangle = \sum_{j''} [(2J+1)(2J'+1)(2k+1)]^{1/2} \left\{ \begin{matrix} J_1 & J_1' & k_1 \\ J_2 & J_2' & k_2 \\ J & J' & k \end{matrix} \right\} \langle \gamma J_1 \| T^{k_1}(\mathbf{A}) \| \gamma'' J_1' \rangle \langle \gamma'' J_2 \| T^{k_2}(\mathbf{B}) \| \gamma' J_2' \rangle \quad [8]$$

$\left\{ \begin{matrix} J_1 & J_1' & k_1 \\ J_2 & J_2' & k_2 \\ J & J' & k \end{matrix} \right\}$ is a Wigner 9-j symbol.

A simplification of the above expression which is often encountered is for the scalar product ($X^k = X^0$) of two commuting tensor operators:

$$\langle \gamma J_1 J_2 JM \| T^k(\mathbf{A}), T^k(\mathbf{B}) \| \gamma' J_1' J_2' J' M' \rangle = (-1)^{J_1' + J_2' + J} \delta_{JM} \delta_{M'M} \left\{ \begin{matrix} J & J_2 & J_1 \\ k & J_1' & J_2' \end{matrix} \right\} \sum_{j''} \langle \gamma J_1 \| T^{k_1}(\mathbf{A}) \| \gamma'' J_1' \rangle \langle \gamma'' J_2 \| T^{k_2}(\mathbf{B}) \| \gamma' J_2' \rangle \quad [9]$$

If a single operator in a coupled scheme of angular momenta acts on only one part (J_1 or J_2) then we have the reduced matrix element expressions:

(a) for operator $T^{k_1}(\mathbf{A})$ operating only on J_1 :

$$\langle \gamma J_1 J_2 J \| T^{k_1}(\mathbf{A}) \| \gamma' J_1' J_2' J' \rangle = (-1)^{J_1' + J_2' + J + k_1} \delta_{J_2 J_2'} \delta_{J_1 J_1'} [(2J+1)(2J'+1)]^{1/2} \left\{ \begin{matrix} J_2 & J_1 & J \\ k_1 & J' & J_1' \end{matrix} \right\} \langle \gamma J_1 \| T^{k_1}(\mathbf{A}) \| \gamma' J_1' \rangle \quad [10]$$

(b) for operator $T^{k_2}(\mathbf{B})$ operating only on J_2 :

$$\langle \gamma J_1 J_2 J \| T^{k_2}(\mathbf{B}) \| \gamma' J_1' J_2' J' \rangle = (-1)^{J_1' + J_2' + J + k_2} \delta_{J_1 J_1'} \delta_{J_2 J_2'} [(2J+1)(2J'+1)]^{1/2} \left\{ \begin{matrix} J_1 & J_2 & J \\ k_2 & J' & J_2' \end{matrix} \right\} \langle \gamma J_2 \| T^{k_2}(\mathbf{B}) \| \gamma' J_2' \rangle \quad [11]$$

For the scalar product of two operators which **both** act on part one (J_1) of a coupled scheme, we have

$$\langle \gamma J_1 J_2 JM \| T^{k_1}(\mathbf{B}) \| \gamma' J_1' J_2' J' M' \rangle = \delta_{JM} \delta_{M'M} \delta_{J_1 J_1'} \delta_{J_2 J_2'} \sum_{j''} (-1)^{J_1' - J_2'} (2J_1 + 1)^{-1} \langle \gamma J_1 \| T^{k_1}(\mathbf{A}) \| \gamma'' J_1' \rangle \langle \gamma'' J_1' \| T^{k_1}(\mathbf{B}) \| \gamma' J_1' \rangle \quad [12]$$

(Continued)

Table 2 Continued

For the relation between operators in space-fixed and molecule-fixed coordinate systems, we use the notation that p gives the space-fixed coordinate and q gives the molecule-fixed coordinate of a tensor operator. The relationship between the same tensor in the two coordinate systems is given by:

$$T_p^k(\mathbf{A}) = \sum_q D_{pq}^k(\alpha, \beta, \gamma)^* T_q^k(\mathbf{A}) \quad [13]$$

where $D_{pq}^k(\alpha, \beta, \gamma)^* = D_{pq}^{k(\omega)*}$ is the complex conjugate of the k th rank rotation matrix $D_{pq}^k(\omega)$. α, β, γ are the three Euler rotation angles that specify the relationship of the molecule-fixed coordinate system to the space-fixed coordinate system. The phase convention used here is opposite to that of Edmonds. The inverse relationship is

$$T_q^k(\mathbf{A}) = \sum_p D_{pq}^k(\omega) T_p^k(\mathbf{A}) = \sum_p (-1)^{p-q} D_{-p, -q}^k(\omega)^* T_p^k(\mathbf{A}) \quad [14]$$

The $D_{pq}^k(\omega)^*$ are simply related to the eigenfunctions of the symmetric top:

$$|JKM\rangle = \left[\frac{2J+1}{8\pi^2} \right]^{1/2} D_{MK}^J(\omega)^* \quad [15]$$

We now quote two additional useful relationships for tensor operators which can be quantized in both molecule – and space – fixed coordinate systems:

$$\langle JKM | D_{pq}^k(\omega)^* | J'K'M' \rangle = (-1)^{K-M} [(2J+1)(2J'+1)]^{1/2} \begin{pmatrix} J & k & J' \\ -K & q & K' \end{pmatrix} \begin{pmatrix} J & k & J' \\ -M & p & M' \end{pmatrix} \quad [16]$$

$$\langle JK || D_{pq}^k(\omega)^* || J'K' \rangle = (-1)^{J-K} [(2J+1)(2J'+1)]^{1/2} \begin{pmatrix} J & k & J' \\ -K & q & K' \end{pmatrix} \quad [17]$$

Note that the Wigner 3-j, 6-j and 9-j symbols are simply numbers when evaluated for particular values of the angular momentum symbols. There are numerous tabulations and programs available which allow their evaluation and the program Mathematica can handle 3-j and 6-j symbols analytically.

Table 3 Rigid rotor classifications.

We classify rigid rotors according to their moments of inertia about three perpendicular axes. There is a convention (due to Mulliken) that the three moments of inertia are labelled ordered according to size by $I_A \leq I_B \leq I_C$ and hence $C \leq B \leq A$

	Moments of inertia	Hamiltonian and energy levels
Spherical tops:	$I_A = I_B = I_C$	$H_r = B\mathbf{J}^2$ $E_r = BJ(J+1)$
Linear molecules:	$I_A = 0 \quad I_B = I_C$	$H_r = B(J_B^2 + J_C^2) = B\mathbf{J}^2$ $E_r = BJ(J+1)$
Symmetric tops:		
Prolate	$I_A < I_B = I_C$	$H_r = AJ_A^2 + B(J_B^2 + J_C^2) = BJ^2 + (A-B)J_A^2$ $E_r = BJ(J+1) + (A-B)K^2$
Oblate	$I_A = I_B < I_C$	$H_r = AJ_A^2 + B(J_B^2 + J_C^2) = BJ^2 + (C-B)J_A^2$ $E_r = BJ(J+1) + (C-B)K^2$
Asymmetric top	$I_A \neq I_B \neq I_C$	$H_{\text{rotation}} = AJ_A^2 + BJ_B^2 + CJ_C^2$ analytic solutions exist for only the first few levels, these solutions are given in Table 4 .

**Figure 1** A simulated spectrum of BrF at 300K. All simulated spectra were generated using Pgopher, courtesy of Dr. CM Western, University of Bristol.

To understand the spectrum we must be able to calculate the absorption frequencies of the lines and their relative intensities. The Beer–Lambert law

$$I(\omega) = I_0(\omega)\exp[-\gamma(\omega)l]$$

describes absorption in a thin sample (after length l is traversed) in terms of the absorption coefficient $\gamma(\omega)$ which is given by:

$$\gamma(\omega) = \frac{8\pi^3}{3hc} \omega \left(\frac{N_m}{g_m} - \frac{N_n}{g_n} \right) |\langle J\Gamma | \boldsymbol{\mu} | J'\Gamma' \rangle|^2 S(\omega, \omega_0)$$

where $S(\omega, \omega_0)$ is a normalized line shape function. Evaluation of $\langle J\Gamma | \boldsymbol{\mu} | J'\Gamma' \rangle$ yields selection rules for the basis functions (see below). For the linear molecule with no electronic angular momentum and no nuclear spin, we can calculate selection rules which tell us whether a particular transition is allowed or not, by

understanding that we are adding a photon angular momentum of one to the angular momentum of the molecule. Therefore, by the formula for addition of angular momenta (see **Table 1**), the change in angular momentum allowed is $\Delta J = 0, \pm 1$ and $\Delta J = 0$ cannot occur from $J = 0$. A complete treatment shows also that $\Delta K = 0, \Delta M = 0, \pm 1$ and the dipole change occurs along the internuclear axis. The possible absorption energies are given by

$$\begin{aligned} \Delta E &= hf = B[J'(J' + 1) - J(J + 1)] \\ &= B[(J + 1)(J + 2) - J(J + 1)] = 2B(J + 1) \end{aligned}$$

So we expect a series of lines separated by $2h$, as shown in **Figure 1**.

The relative intensities of the lines also depend upon the difference in population of the two levels concerned at the temperature considered, $N_m/g_m - N_n/g_n$ (g_n is the

degeneracy of level n , etc.). For a sample in thermal equilibrium the relative populations are given by the Boltzmann distribution

$$N_m/g_m = (N_n/g_n)\exp[-(E_n - E_m)/kT]$$

and this factor accounts for the envelope of the spectral intensities shown.

In the case of a molecule with two identical nuclei (such as CO_2), relative line intensities are affected by the nuclear spins. The nuclear spin governs the intensities through the generalized Pauli exclusion principle; 'all wavefunctions are antisymmetric with respect to the interchange of fermions (half-integer spin particles) and symmetric with respect to the interchange of bosons (integer spin particles)'. A general treatment uses the molecular symmetry group. For a linear molecule with zero spin nuclei the antisymmetric rotational levels are missing entirely. In the case of CO_2 the Σ_g^+ electronic state has only even J levels. If only one pair of identical nuclei have nonzero spins, then the ratio of the statistical weights of the symmetric and antisymmetric rotational levels is $(I+1):I$ for bosons or $I:(I+1)$ for fermions.

The rotational constant B is easily determined from the spectrum. For a diatomic molecule, B is given by the expression

$$B = \left\langle \frac{\hbar^2}{2\mu R^2} \right\rangle = \frac{\hbar^2}{2\mu} \left\langle \frac{1}{R^2} \right\rangle$$

where μ is the reduced mass, R is the bond length and the angled brackets show that an average value (expectation value) must be calculated. Back calculation yields the expectation value of $1/R^2$, but inverting this and taking the square root does NOT give the expectation value of R , even for a harmonic oscillator! For linear molecules with more than one atom, isotopic substitution can be used to find different B values, and hence the expectation values of $1/R^2$ for several different bonds can be found simultaneously.

Symmetric Top Molecules

We consider molecules to be symmetric tops if two of their moments of inertia are the same. It is useful to consider two cases separately, the 'prolate' and 'oblate' symmetric tops. A diagram of the lowest energy levels of both prolate and oblate symmetric tops is given in **Figure 2** (center and right). The selection rules for a symmetric top are the same as for a linear molecule: $\Delta J = 0, \pm 1$ and $\Delta J = 0$ cannot occur from $J = 0$, $\Delta K = 0$, $\Delta M = 0, \pm 1$ and the dipole change occurs along the symmetry axis.

Asymmetric Top Molecules

The energy levels of an asymmetric top molecule cannot in general be expressed in a simple algebraic form. Those levels for which such simple solutions exist are given in **Table 4**. The complication arises because the functions $|JKM\rangle$ which we are using as our basis are NOT eigenfunctions for the asymmetric top. However, many asymmetric rotors are nearly a prolate or oblate top, and the perturbations to the energy levels in such cases may be quite small. **Figure 3** shows a schematic correlation diagram between the energy levels in each case. The levels of the asymmetric rotor are usefully LABELLED by the number $\tau = K_A - K_C$ which is NOT a quantum number, but has the useful property that its value increases with increasing energy of the levels. Note that levels of a given J do not cross.

The general problem of finding the allowed energies and transition intensities of the asymmetric rotor is solved by setting up the Hamiltonian matrix and the dipole transition matrix (the 'D' matrix) using the $|JKM\rangle$ functions as a basis. The Hamiltonian matrix is not now diagonal but by diagonalizing the Hamiltonian matrix we find the eigenvalues and eigenvectors of the Hamiltonian that we have used. The eigenvalues can be used to extract the relative intensities of all allowed

$4_{1,4}$	$5A+5B+10C-2[4(A-B)^2+9(A-C)(B-C)]^{1/2}$
$4_{0,4}$	no analytic solution
$5_{4,2}$	$10A+10B+10C+6[(B-C)^2+(A-B)(A-C)]^{1/2}$
$5_{2,4}$	$10A+10B+10C+6[(B-C)^2+(A-B)(A-C)]^{1/2}$

transitions from the 'D' matrix. The magic of this approach is that we *do not need to know the eigenfunctions themselves*. The diagonalization provides the mixture coefficients for the basis that we have chosen (a'_K) without us having to specify the basis functions apart from their properties under various quantum mechanical operators, i.e. their matrix elements. The properties of the basis functions are given in **Table 1** and in spherical tensor form in **Table 2**. For more general problems where the molecule (and therefore the Hamiltonian) includes electron or nuclear spins, it is not possible to write an eigenfunction which describes the property in three-dimensional space, but it is still possible to set up and diagonalize the Hamiltonian and D matrices.

Vibration–Rotation Interaction

In some sense we can understand a spectrum if we can assign values of A , B , C which generate the spectral line positions using the selection rules. The best test of this fit

is to examine if the tested and predicted transitions agree with one another. A spectrum has not been correctly fitted unless the constants which have been determined can reproduce the experimental transition frequencies to within the experimental accuracy. From our initial study, we know that B is a measure of $\langle 1/R^2 \rangle$, averaged over the particular electronic and vibrational state involved. In order to fit the experimental data accurately it is usually necessary to consider a more general energy level expression. This is achieved by adding terms to the Hamiltonian which allow for the interaction of vibration and rotation. When a molecule rotates, the centrifugal forces distort the molecule and this changes the moments of inertia. In a linear molecule the effect can be seen as a slight decrease in the spacing between successive rotational lines as J increases. The effect for low J lines is usually less than 1 part in 10^4 , but such changes are observable.

In linear molecules we account for the interaction by changing the rotational Hamiltonian to

$$H_{\text{rotation}} = BJ^2 - DJ^4 + HJ^6 + KJ^8 + LJ^{10} + \dots$$

giving rise to the new eigenvalue expressions:

$$E_{\text{rotation}} = B[J(J+1)] - D[J(J+1)]^2 + H[J(J+1)]^3 + K[J(J+1)]^4 + L[J(J+1)]^5 + \dots$$

As many terms as necessary are used in order to fit the spectrum. Unfortunately such power series expressions are heavily correlated – this manifests itself when say, B and D are determined if a further power is added, the values of B , D and H are now determined, but the values of B and D are not the same as before.

For nonlinear molecules, the Hamiltonian including the effects of vibration–rotation interaction is more complicated, but well understood.

Molecules with Electronic Angular Momentum

In this section we shall only consider the additional complications caused in diatomic molecules but similar considerations apply to more complicated molecules. So far we have considered molecules which have no angular momentum due to their electrons: that is no electronic angular momentum. The addition of spin angular momentum into the problem changes the energy level expressions and causes additional splittings of lines; the ground electronic state of O_2 is $^3\Sigma$ and therefore has two unpaired electron spins yielding a total spin of 1. Each rotational level with $J > 1$ is now split into three and each line in the spectrum involving $J > 1$ is split into six components, three of which are intense (hence the name 'triplet').

Figure 3 Correlation between the energy levels of prolate, oblate and asymmetric tops. Reproduced from Figure 2.11 of Gordy W, Smith WV, and Trambarulo RF (1953) *Microwave Spectroscopy*, p. 110. New York: Wiley.

Figure 4 Simulated rotational spectrum of the NO ground state (X^2II) – note that the first rotational line is 'missing' due to the electronic angular momentum $\Lambda = 1$ (II-state); such missing lines aid the assignment of electronic states.

Orbital electronic angular momentum gives rise to non-sigma electronic states, such as $^2\Pi$ states which have an orbital angular momentum of 1 and a spin angular momentum of $\frac{1}{2}$. NO is a molecule with a $^2\Pi$ ground electronic state and a simulated rotational spectrum of NO is shown in **Figure 4**.

One now has a choice of how to construct a basis set in which to set up the Hamiltonian, and the best basis is the one which most nearly diagonalizes the Hamiltonian matrix. However, nature does not care which basis we

Vector coupling diagram for Hund's case (a).

Vector coupling diagram for Hund's case (b).

Figure 5 Vector diagrams for Hund's coupling cases *a* and *b*. Reproduced from Figures iii.17 and iii.18 of Carrington A (1973) *Microwave Spectroscopy of Free Radicals* pp. 129–130. New York: Academic.

choose and a full calculation in any basis yields the same results; which basis is chosen is purely a matter of convenience. In diatomic molecules the choices of basis for the inclusion of spin most normally used were first considered by Hund, and are called Hund's cases *a* and *b* (see **Figure 5** for explanation).

We shall only consider Hund' case *a*. We are creating a basis function by coupling together the angular momenta in a particular order: $\mathbf{L}$ and $\mathbf{S}$ (the electronic and spin angular momentum of the electrons) are strongly coupled to the internuclear axis, and have projections Λ and Σ on this axis. The combination of $\Lambda + \Sigma = \Omega$. The angular momentum along the internuclear axis (r) is Ωr which is coupled with the angular momentum of the rotating nuclear framework ($\mathbf{R}$) to give the resulting total angular momentum (excluding nuclear spins) of $\mathbf{J}$. In the case of the diatomic molecule, the projection quantum number K is called Ω in Hund' case *a* and the eigenfunctions are labelled as $|J\Omega M\rangle$ rather than $|JKM\rangle$. The full eigenfunction includes the dependence on electron spin and can be written as the simple product function $|\Sigma\rangle |J\Omega M\rangle = |\Sigma; J\Omega M\rangle$. The fact that we can simply multiply the two functions together in this way (one for electron spin, one for resultant angular momentum) makes calculation of some matrix elements extremely simple. The total eigenfunction, including the electronic and vibrational state involved, is written $|v, \Lambda, \Sigma; JKM\rangle$.

Extra Terms in the Hamiltonian

The inclusion of electron spin into the problem increases the complexity of the Hamiltonian which must be considered. In general, we must now add the following terms to the rotational Hamiltonian, some of which may be zero in a particular problem

$$H_{\text{fine structure}} = H_{\text{spin-spin}} + H_{\text{spin-orbit}} + H_{\text{spin-rotation}} + H_{\text{lambda doubling}}$$

Hyperfine Interactions

If the nuclei in a molecule have angular momenta $I_n > 1$ then complications in the spectra may arise due to the electric quadrupole field of the nuclei. Such additional structure is commonly observed and arises because there is an interaction between the electric field gradient along the internuclear axis (due to the electrons), the electric quadrupole moment of the nucleus, and the angular momentum of the molecule. The energy change due to the quadrupole moment can be written:

$$E_{\text{quadrupole}} = -eqQf(I, J, F)$$

where $-eqQ$ is the nuclear quadrupole moment multiplied by the field gradient and $f(I, J, F)$ is an angular momentum coupling coefficient called Casimir's

Figure 6 Additional structure in a single rotational line ($J=3-2$) of BrF due to the quadrupolar constant $eqQ=909.2\text{MHz}$ of the bromine nucleus ($I=3/2$).

function. The effect of the quadrupole interaction on a spectral line is shown in **Figure 6**.

If a molecule has nonzero spin angular momentum, then magnetic hyperfine interactions may be observed between any nuclei with nonzero spin and between such nuclei and the electron spins. Such interactions cause the zero-field splittings in NMR.

The additional terms which must be considered due to magnetic hyperfine interactions are as follows:

$$H_{\text{hyperfine}} = H_{\text{fermi-contact}} + H_{\text{spin-dipole, nuclear dipole}} \\ + H_{\text{nuclear dipole-nuclear dipole}}$$

there are other possible terms, but they have not commonly been necessary in interpreting the spectra which have been observed. Typically, hyperfine interactions have magnitudes which lead to splittings in spectra between 1 and 1000 MHz.

Frequencies and Intensities of Transitions

To calculate the relative intensity of a particular transition we use the interaction Hamiltonian between the dipole moment of the molecule and the electric vector of the radiation: $H_{\text{interaction}} = -\mathbf{E} \cdot \boldsymbol{\mu}$. We need to calculate the matrix elements of this interaction using the eigenfunctions for the states of interest. In the simplest cases we have considered our eigenfunctions are the functions $|JKM\rangle$ and we need to calculate the matrix elements $\langle v, \Lambda, S\Sigma; JKM | -\mathbf{E} \cdot \boldsymbol{\mu} | v, \Lambda, S'\Sigma'; J'K'M' \rangle$; the intensity of the transition is proportional to the square of this

matrix element. The procedure is to expand the scalar product in space-fixed axes using eqn [3] – both $\mathbf{E}$ and $\boldsymbol{\mu}$ are 1st rank tensors (vectors):

$$\mathbf{E} \cdot \boldsymbol{\mu} = T^1(\mathbf{E}) \cdot T^1(\boldsymbol{\mu}) = \sum_p (-1)^p T_p^1(\mathbf{E}) T_{-p}^1(\boldsymbol{\mu})$$

and we insert this into the matrix element

$$\langle v, \Lambda, S \sum; JKM | - \sum_p (-1)^p T_p^1(\mathbf{E}) T_{-p}^1(\boldsymbol{\mu}) | v,$$

$$\Lambda, S' \sum; J'K'M' \rangle$$

as the electric field does not operate on the basis states, we can take the electric field outside the matrix element:

$$- \sum_p (-1)^p T_p^1(\mathbf{E}) \langle v, \Lambda, S \sum; JKM | T_{-p}^1(\boldsymbol{\mu}) | v,$$

$$\Lambda, S' \sum; J'K'M' \rangle$$

To evaluate the matrix element we need to transform the tensor for the dipole moment into molecule fixed coordinates, which we can do using eqn [13]

$$T_{-p}^1(\boldsymbol{\mu}) = \sum_q D_{-p,q}^1(\omega)^* T_q^1(\boldsymbol{\mu})$$

which gives us:

$$- \sum_{p,q} (-1)^p T_p^1(\mathbf{E}) \langle v, \Lambda, S \sum; JKM | D_{-p,q}^1(\omega)^* T_q^1(\boldsymbol{\mu}) | v,$$

$$\Lambda, S' \sum; J'K'M' \rangle$$

Now $T_q^1(\mu)$ only operates on v, Λ and $D_{-p,q}^1(\omega)^*$ only operates on $|JKM\rangle$, and neither operator effects $|S\Sigma\rangle$ so we can separate this out to:

$$-\sum_{p,q} (-1)^p T_p^1(E) \langle v, \Lambda | T_q^1(\mu) | v, \Lambda \rangle \\ \times \langle JKM | D_{-p,q}^1(\omega)^* | J'K'M' \rangle \langle S \sum | S' \sum' \rangle$$

$T_p^1(E)$ is a constant number which tells us the intensity of the light and (through p) its polarization; $\langle S\Sigma | S'\Sigma' \rangle$ yields the condition that $S=S'$ and $\Sigma=\Sigma'$ if the expression is nonzero; $\langle v, \Lambda | T_q^1(\mu) | v, \Lambda \rangle$ is constant for a particular state, and so (finally) it is the matrix elements $\langle JKM | D_{-p,q}^1(\omega)^* | J'K'M' \rangle$ (which are the elements of the 'D-matrix') which determine the relative intensities of the transitions and the selection rules. Using eqn [16] (Table 2) we evaluate the D-matrix elements to:

$$(-1)^{K-M} [(2J+1)(2J'+1)]^{1/2} \\ \times \begin{pmatrix} J & 1 & J' \\ -K & q & K' \end{pmatrix} \\ \times \begin{pmatrix} J & 1 & J' \\ -M & -p & M' \end{pmatrix}$$

The selection rules arise from the properties of the 3-j symbols which yield $\Delta J=0, \pm 1$. The selection rule on K depends upon which components of the dipole moment are nonzero but, as $q = -1, 0, 1$ only, then $\Delta K=0, \pm 1$. The selection rule on M depends on the polarization of the light. For z polarized light $p=0$ and $\Delta M=0$. For nonpolarized light $\Delta M=0, \pm 1$.

In more complicated cases, where the eigenfunctions are linear combinations of the basis functions, the relative intensities are found by multiplying the D-matrix by the eigenfunction coefficients.

The frequencies of transitions are found by setting up the requisite Hamiltonian matrix in the same basis and diagonalizing it, evaluation of the matrix elements of the Hamiltonian matrix is accomplished in the same fashion as for the example above. The eigenvectors and eigenvalues found together with the D-matrix enable a complete calculation of the spectrum to be made.

Summary

We have considered the theory necessary to understand rotational spectroscopy, concentrating on some simple cases. In a first approximation, spectra can be understood on the basis of rigid rotor models. Allowing for the fact that molecules are not rigid complicates spectra and introduces new molecular constants. We have seen that when electronic spin and orbital angular momenta are included in the picture we need to extend our basis sets, and the utility of spherical tensors has been illustrated in calculating expressions which yield the relative intensities of rotational transitions.

Introduction

In conventional microscopy, resolution is limited in the x , y , and z directions (where x and y are in the imaging plane and z is aligned with the optical axis). Similarly, in conventional fluorescence microscopy, excitation can occur out of the focal plane, leading to problems with high background.

Resolution in the x - y Plane

Resolution in an imaging system is often defined by the Rayleigh criterion:

$$r = \frac{1.22\lambda_0}{2NA} \quad [1]$$

Here r is the resolution limit, λ_0 is the vacuum wavelength of the light used, and NA is the numerical aperture of the objective lens. For example, for light at 600 nm the resolution is 261 nm for a lens with numerical aperture of 1.4. Although this definition of resolution is essentially arbitrary, it emphasizes the way in which resolution is limited by diffraction. Recently, several approaches have been developed by which this limit may be overcome in far-field

imaging – so-called ‘super-resolution’ imaging techniques. However, near-field optics offers an alternative approach to the problem, as described in the following text.

Selectivity in z

The most popular method for eliminating out-of-focus background light is to use confocal microscopy. Here illumination and detection are through a pinhole that is in a plane optically conjugate with the sample. This eliminates the majority of the out-of-focus illumination, improves contrast, and enables selectivity of illumination in the z direction (so-called optical sectioning). This permits, for example, three-dimensional reconstructions of cells to be made from a ‘stack’ of images at different z positions. In contrast, near-field approaches can allow greater selectivity in the z -axis, albeit near a surface and without the same level of three-dimensional information.

Near-Field Techniques

This article will cover a variety of near field microscopy and spectroscopy techniques that are used to improve resolution or selectivity:

- total internal reflection fluorescence microscopy (TIRFM),
- scanning near-field optical microscopy (SNOM),
- tip-enhanced Raman (or fluorescence) spectroscopy (TERS/TEFS).

Total Internal Reflection Fluorescence Microscopy

TIRFM and its many variants are used principally to excite fluorescence in a very thin layer near a surface (such as a microscope slide). The main applications are in cell biology and single molecule detection. TIRFM can be implemented with relatively straightforward modifications to a conventional fluorescence microscope, and commercial TIRF accessories are now available for the main brands of

research microscope. The following sections review the theory, implementation, and applications of this technique.

Total Internal Reflection

Internal reflection occurs when light propagating in a medium (such as glass) encounters an interface with a more rarefied medium (such as water or air) – that is, a medium with a lower refractive index. At the interface, the light may be reflected or transmitted. The angle of the transmitted ray can be found from the familiar ‘Snell’s law’ for refraction:

$$n_2 \sin \theta_i = n_1 \sin \theta_t \quad [2]$$

where n_1 is the refractive index of the first medium and θ_i is the angle of incidence; n_2 is the refractive index of the second medium and θ_t is the angle of the transmitted ray. The angle of the reflected ray, θ_r , is equal to θ_i .

For internal reflection, the angle of the transmitted ray is always greater than the angle of incidence (except at normal incidence); however, the angle of the transmitted ray obviously cannot exceed 90° as this would mean that the ray would reenter the first medium. The angle of incidence at which $\theta_t = 90^\circ$ is known as the critical angle and can be calculated as follows. By rearranging eqn [2],

$$\sin \theta_i = \frac{n_1}{n_2} \sin \theta_t \quad [3]$$

Since $\sin 90^\circ = 1$, the critical angle is then given by

$$\theta_c = \theta_i = \sin^{-1} \left(\frac{n_1}{n_2} \right) \quad [4]$$

For example, for a quartz-water interface ($n_1 = 1.33$ and $n_2 = 1.46$) the critical angle is 65.6° .

At angles greater than the critical angle, the transmitted ray ceases to exist, and the entire incident light is reflected. This is the condition known as total internal reflection. At first glance, if no light is transmitted into the sample, one might expect that no fluorescence could be excited. In fact some energy does penetrate into the sample, in the form of an evanescent wave – this is an example of a near-field optical effect. It is the particular properties of this evanescent wave that make it so useful (Figure 1).

If there is no absorption or scattering at the interface, all the energy passes into the reflected light. This helps to greatly reduce the background from excitation light. However, if energy is absorbed from the evanescent wave it can excite fluorescence in the normal way.

Penetration Depth

The chief feature of the evanescent wave that makes it so useful is the fact that its intensity decays exponentially

Figure 1 Total internal reflection and the evanescent wave. A schematic view of the evanescent wave (not to scale). A laser beam (shown in green) is incident on the interface between an optically dense medium (refractive index n_2) and the sample (refractive index n_1). Here the angle of incidence, θ_i , is greater than the critical angle, θ_c ; an evanescent wave is generated at the interface. The intensity, I , of this evanescent wave decays exponentially with the distance, z , away from the interface. The penetration depth, d , represents the distance at which the intensity falls to $1/e$ times the intensity at the interface. The figure also illustrates the two orthogonal incident polarizations s and p , and the directions of the x and z axes referred to in the text (the y axis points out of the page).

with depth into the second medium:

$$I(z) = I(0)e^{-z/d} \quad [5]$$

where z is the distance into the second medium, $I(0)$ is the intensity at the interface, and $I(z)$ is the intensity at depth z . The parameter d is referred to as the penetration depth and is the depth at which the intensity falls to $1/e$ times the intensity at the interface. The penetration depth depends on the refractive indices of the media, the angle of incidence, and the wavelength of the light:

$$d = \frac{\lambda_0}{4\pi} (n_2^2 \sin^2 \theta_i - n_1^2)^{-1/2} \quad [6]$$

The penetration depth is a fraction of the wavelength for most angles greater than the critical angle. This extreme z -sectioning or selectivity of excitation is the chief advantage of the evanescent wave method. Note also that the penetration depth can be controlled by adjusting the angle of incidence, the wavelength of the light, or the refractive indices of the media – but in most experimental designs the angle of incidence will be the most useful parameter that can be varied.

Intensity and Polarization

Next, the intensity of the evanescent wave is considered – how is it related to the intensity of the incident beam? To answer this fully, the polarization of both the incident light and the evanescent wave must be considered.

The two orthogonal linear polarizations of the incident light are s (perpendicular to the plane of incidence)

and p (parallel to the plane of incidence). For s -polarized light, the electric field vectors are oriented solely along the y -axis, whereas for p -polarization, there will be components along both the z - and x -axes. Correspondingly, for s -polarized incident light of intensity $\mathcal{I}_s$, the intensity of the evanescent wave in the y direction is

$$I_y(0) = \mathcal{I}_s \frac{4 \cos^2 \theta_i}{1 - n^2} \quad [7]$$

where $I_y(0)$ indicates the intensity at the interface (where $z=0$) and n is the ratio of the two refractive indices, n_1/n_2 . Similarly, the x and y components are related to $\mathcal{I}_p$, the incident p -polarized intensity, as follows:

$$I_x(0) = \mathcal{I}_p \frac{4 \cos^2 \theta_i (\sin^2 \theta_i - n^2)}{n^4 \cos^2 \theta_i + \sin^2 \theta_i - n^2} \quad [8]$$

$$I_z(0) = \mathcal{I}_p \frac{4 \cos^2 \theta_i \sin^2 \theta_i}{n^4 \cos^2 \theta_i + \sin^2 \theta_i - n^2} \quad [9]$$

(see **Figure 2**). The most striking feature of this plot is that near the critical angle, the z and y evanescent intensities are four or more times higher than the incident intensities! This somewhat counterintuitive effect further enhances the signal-to-noise ratio of the technique. Away from the critical angle, the intensities fall off rapidly; the x intensity is always much weaker than the others. For incident light where the s and p intensities are equal, the x , y , and z components will be as shown (e.g., where the

incident light is linearly polarized at 45° or circularly polarized); for pure s -polarized input there will only be the y component, and for p -polarized input there will only be the x and z components.

The evanescent intensities may also be expressed in terms of the s and p components, where the s component is the same as the y component:

$$I_s(0) = I_y(0) = \mathcal{I}_s \frac{4 \cos^2 \theta_i}{1 - n^2} \quad [10]$$

and the p component is the sum of the x and y components:

$$I_p(0) = \mathcal{I}_x(0) + I_z(0) \quad [11]$$

which gives

$$I_p(0) = \mathcal{I}_p \frac{4 \cos^2 \theta_i (2 \sin^2 \theta_i - n^2)}{n^4 \cos^2 \theta_i + \sin^2 \theta_i - n^2} \quad [12]$$

The exponential decay and the penetration depth are unaffected by polarization; the effect of polarization is simply to change the value of $I(0)$ in eqn [5].

In summary, the intensity and polarization at the interface are influenced by the angle of incidence, the refractive indices of the media, and the intensity and polarization of the incident light. The practical implications are that if the experimental design requires, the polarization of the evanescent wave can be controlled – within certain limits – by changing the polarization of the incident beam, for example, using waveplates.

In real world applications, the situation may be somewhat more complex than described previously: for example, real beams have a finite width; they may not be

Figure 2 Intensity of the evanescent wave versus angle of incidence and polarization. This plot illustrates how the relative intensity of the evanescent wave is related to the incident intensity at different angles of incidence. Near the critical angle, the intensity of the y and z components is several times greater than the incident intensity, whereas the x component is always weak. The s -polarized component of the evanescent wave consists of the y intensity, whereas the p -polarized component is the sum of the x and z components.

perfectly collimated; and they are likely to show a non-uniform intensity profile. However, for most practical purposes these effects may be neglected.

Implementation

TIRF is usually implemented in a light microscope system. There are two main approaches to this, which are used in the vast majority of custom-built and commercial setups, although each approach has several variations. The essential difference between the techniques is the means by which the fluorescence excitation light (usually a laser) is introduced into the sample chamber (**Figure 3**).

Prism-Based TIRF

In this method, a prism is used to couple the incoming beam into a microscope slide (**Figure 3**). The main function of the prism is to allow the beam to enter at near-normal incidence; the prism is typically optically coupled to the slide with a medium such as glycerol, so that the total internal reflection occurs at the surface of a microscope slide. This design is simple to set up, affords great freedom of control over the angle of incidence, and potentially gives the least concern over scattered excitation light contributing to the background. The principal disadvantage is that because the evanescent wave is

Figure 3 Schematic of TIRF configurations. This schematic illustrates the most common configurations used in TIRF microscopy. In prism-based TIRF (1), a prism is used to couple a collimated laser beam into a microscope slide such that it reaches the slide surface at an angle greater than the critical angle. In objective TIRF (2), the beam is instead focused at the periphery of the back aperture of a high numerical aperture microscope objective.

generated at the slide surface, the fluorescence is being viewed through the thickness of the specimen. With typical high NA oil-immersion objectives, spherical aberration creates difficulties with viewing through thick specimens and therefore very thin (of the order of 10 μm) samples are required. This makes this technique poorly suited for cell work. Also the prism restricts access to the far side of the microscope slide, making it difficult to combine this technique with other methods such as bright-field microscopy. A final concern is that the laser beams propagating in free space above the microscope stage may present a safety hazard and therefore such designs are not suited to off-the-shelf systems.

Prismless or Objective TIRF

This is the design that has become most popular and is used in the majority of commercial systems; it is also the preferred design for working with cells (**Figure 3**). The laser beam that is used to excite fluorescence is brought to a focus at a point in the back focal plane of a high NA objective lens, so that a parallel beam emerges. By choosing a focal position near the edge of the back aperture, the beam emerges at high angle and undergoes total internal reflection at the surface of the microscope cover slip. This method has many advantages. Because high NA oil-immersion objectives are corrected to image specimens through the thickness of a standard cover slip, and the evanescent wave is generated, and fluorescence is excited in just this location, the thickness of the specimen ceases to become an issue. This means, for example, that cells can be visualized in tissue culture flasks. Also, unrestricted access to the upper side of the specimen permits this method to be combined with other forms of illumination or techniques such as optical tweezers, bright field, or DIC microscopy. Unlike the prism-based method, the laser beams are contained (provided that the system is correctly aligned) and complicated realignment is not necessary when changing specimens. The chief limitations of the method are that the range of angles of incidence that can be used are constrained by the design of the objective lens, and that any scattering of the laser light in the objective lens will give rise to a higher background signal. However, the advantages of this design are such that it is now offered as an option by the majority of the microscope manufacturers, and some third-party suppliers.

Cell Biology Applications

Since the original development of the technique, TIRF has been used for cell biology applications. Particularly attractive are the facility to selectively study processes and structures at the basal membrane of the cell, such as focal adhesions. It has also been used in studies of exocytosis. The advantage of TIRF here is that nonspecific

sources of fluorescence, such as autofluorescence from cellular components and out-of-focus fluorescence from elsewhere in the cell are virtually eliminated. The ultimate is of course the fluorescence imaging of single molecules in living cells, which has now become an established (if not a routine) technique.

Single-Molecule Detection

The elimination of background fluorescence achieved by TIRF overcomes one of the main difficulties in detecting single molecule fluorescence. However, the fluorescence signal from a single molecule is still tiny – typically a few thousand photons per second – and very sensitive low-noise cameras are required. Typically, either an intensified CCD or an electron multiplying CCD camera are used. Most users adopt such an imaging approach; however, in some applications single-point detectors such as avalanche photodiodes are used. For example, TIRF may be combined with fluorescence fluctuation spectroscopy to perform a hybrid technique known as TIR-FCS.

Scanning Near-Field Optical Microscopy

SNOM, also known as near-field scanning optical microscopy (NSOM), is an optical version of the stethoscope, a device that can locate the source of a sound with positional precision better than one-hundredth of the wavelength of that sound. Similarly, using near-field optics, one can achieve spatial resolution better than the diffraction limit. In principle, spatial resolution can be improved by collecting the optical signal from a smaller region and building the image pixel by pixel. Alternatively, one can illuminate the sample pixel by pixel with a small spot size and build the image in the same way. This can be implemented by two schemes:

1. illuminate the sample surface with a near-field probe and collect the signal in far-field, or
2. illuminate the surface in far-field and collect the signal in near-field.

The probe tracks the surface being imaged; however, it needs to be held within a few nanometers of the surface. Therefore, a topographic image of the surface is also acquired along with the optical image. Since an AFM is used to implement the technique, SNOM is often considered to be a scanning probe microscopy (SPM) technique. The probe for performing this technique is a specially fabricated optical fiber with a nanoscopic aperture through which light can be sent or collected; these are called aperture probes, and the technique is called aperture-SNOM (a-SNOM). Instead of using an aperture probe, a sample can also be illuminated with an

apertureless metal tip where the enhanced electric field at the end of the tip generates near-field signal at the tip-sample interface. This technique is often called scattering-SNOM (s-SNOM). Spatial resolution of both a-SNOM and s-SNOM is an order of magnitude better than the far-field resolution. A unique advantage of SNOM is that it can perform high resolution imaging at ambient conditions, unlike electron microprobes where the sample needs to be in vacuum.

Aperture SNOM

a-SNOM can be implemented in a variety of different configurations – the most commonly used configuration is shown in **Figure 4**. The nanoscopic probe is a truncated glass cone ($\epsilon = 2.25$) coated with aluminum ($\epsilon = 34.5 + i8.5$). The sample is a transparent glass cover slip or microscope slide. Linearly polarized laser light is coupled to the other end of the glass fiber. a-SNOM has been widely used to study organic thin films; the relative orientation of the polarization axis of the laser and orientation of the molecules in the film determine the absorption of the laser beam, and therefore generate contrast in the SNOM image. Fluorescently labelled cell surfaces have also been studied using a-SNOM. Often a-SNOM images are affected by the topography of the surface. Therefore, care is required in distinguishing SNOM images from artifacts.

Figure 4 Schematic diagram of a-SNOM. This schematic is an example of near-field illumination and far-field collection.

Scattering SNOM

In s-SNOM a sharp metal-coated tip is used instead of an aperture probe. Gold-coated cantilever tips have been commonly used for s-SNOM. s-SNOM intensity depends on the tip diameter, tip-sample distance, and dielectric properties of the tip (ϵ_t) and the sample (ϵ_s) by the following relationship:

$$E^{nf} \propto \alpha_{eff} E_i = \frac{\alpha(1+\beta)}{1 - \frac{\alpha\beta}{16\pi(a+z)}}$$

$$\text{where } \alpha = 4\pi a^3 \frac{(\epsilon_t - 1)}{(\epsilon_t + 2)}, \epsilon_s = \frac{(1+\beta)}{(1-\beta)} \quad [13]$$

Therefore, an s-SNOM image essentially is a map of the dielectric functions of the materials. For example, in a mixture of domains of gold and nickel, nickel appears darker than gold, whereas in a mixture of domains of nickel and chromium, nickel appears brighter than chromium. The spatial resolution of s-SNOM depends on the size of the tip end; it is the aperture size that determines spatial resolution of an a-SNOM. An oscillating cantilever probe is used instead of a fiber probe. The near-field signal is extracted from the mixture of far-field and near-field signals using a lock-in amplifier. Often interference techniques (homodyne and heterodyne detection) are also used to improve the signal to noise ratio. s-SNOM images are normally less affected by topography. Only a good feedback control of the AFM system can reduce the effect.

Tip-Enhanced Raman Spectroscopy

Raman spectroscopy is a powerful tool to characterize structure and chemistry of a surface. It is an inelastic scattering process where Raman active phonons of the sample alter the frequency of incident photons. A Raman spectrum is a plot of the intensity of scattered light with the shift in frequency. A position of a Raman peak directly measures the frequency of the corresponding phonon. Generally, the Raman signal is very weak — one scattered photon carrying a Raman signal is generated for every one million incident photons. In surface enhanced Raman spectroscopy (SERS), signal strength is enhanced by coupling incident photons with a surface plasmon of a noble metal such as silver, gold, or platinum.

TERS is another class of high-spatial-resolution optical spectroscopy technique. In a way, it is combination of SNOM and SERS. Like a-SNOM, high-spatial-resolution Raman spectra can also be obtained by sending the laser beam through a narrow aperture, however, the signal is normally very weak.

Figure 5 Schematic of the optical path of a TERS setup in transmission mode.

TERS (first reported in 2001) is more popular due to the stronger Raman signal and high signal enhancement at the tip end due to surface plasmon resonance. In this type of set up (**Figure 5**), a gold or silver tip is illuminated with a laser beam having wavelength λ , such that $hc/\lambda = \text{energy of the surface plasmon of the tip}$. Often, a red laser is used in combination with a gold tip or a green laser is used in combination with a silver tip to achieve the surface plasmon resonance. The polarization of the laser beam is aligned along the axis of the tip. When the electric field of the incident photon is coupled with the surface plasmon of the tip, there is significant enhancement of the electric field at the tip end, which, in turn, generates a strong Raman signal from an area similar to the size of the tip. The Raman signal is then collected in the far-field and sent to a Raman spectrometer. In a scanning type system, such a Raman signal can be obtained from every pixel of the scan, and a TERS image can be formed using the intensities of specific Raman peaks. It is also common to use a single channel detector such as a single-photon counting module instead of a spectrometer, which detects the Raman signal more efficiently. Similar to the Raman signal, a fluorescence signal can also be detected (this is known as TEFS). This technique has been used to image quantum dots and fluorescent molecules. Since electric field enhancement takes place at the end of the tip, the size of the tip limits the spatial resolution of a TERS image. The contrast of a TERS image depends on the Raman enhancement factor of the tip. A Raman enhancement factor is proportional to $(E^{nf}/E^i)^4$ and it is measured considering Raman intensities with the tip near the surface, tip away from the surface, size of the laser spot at the focal point, and size of the tip. TERS has been used to study various nanostructures, fluorescent molecules, and amino acids. It is possible to use the technique to measure structure and chemistry of a variety of Raman active materials at high spatial resolution.

Conclusion

A variety of techniques based on near-field optics offer powerful tools for increasing the spatial selectivity and resolution of fluorescence and Raman measurements. TIRF uses near-field excitation of fluorescence to achieve highly z -selective detection of fluorophores near a surface. The enhanced signal-to-noise ratio thus obtained permits the detection, imaging, and spectroscopy of single fluorescent molecules, both *in vitro* and within living cells. Furthermore, it provides a powerful method for specifically imaging structures and processes near to the basal surface of a cell.

The two variants of SNOM, namely a-SNOM and s-SNOM, allow optical imaging at a spatial resolution (in the x - y plane), which is an order of magnitude better than normal far-field imaging. s-SNOM images map out the dielectric contrast of a surface under ambient conditions, which is a unique advantage of the technique. TERS provides more structural and chemical information with a higher spatial resolution than SNOM. These techniques have the potential to be used in a variety of areas including materials science, chemistry, and biology.

ω	vibrational frequency

The atomic resolution and spectroscopic capabilities of scanning probe microscopes (SPMs) have enabled elucidation of the great heterogeneity of surface sites including defects, step edges, lattice impurities, adsorbates, and grown structures. One or more of these minority sites often function as the active sites for surface processes, and their individual investigation is thus required to gain insight into such processes. Such specific information cannot typically be acquired by spectroscopies that measure ensemble averages of the surface.

The scanning tunnelling microscope (STM) is the most suited, and the most developed of the various SPMs, to perform local spectroscopic measurements. The development of STM in 1981 resulted in its inventors, Binnig and Rohrer, being awarded the Nobel prize for physics in 1986 (see Further Reading section). Discussion of STM techniques will constitute the bulk of this article. It also has the most restricted range of accessible substrates in terms of conductivity and roughness. The atomic force microscope (AFM) has limited spectroscopic capabilities but can image a wider range of samples. The near-field scanning optical microscope (NSOM) has excellent spectroscopic, but limited spatial resolution. These latter two SPMs are discussed at the end of this article.

The basic working principles of the STM rely on the quantum mechanical properties of electrons. When an atomically sharp metal probe tip is brought within a few Å of a conducting or semiconducting surface, electrons can tunnel through the energy barrier between the probe tip and surface. By applying a constant DC bias voltage

(V), a net tunnelling current (I) can be induced between the probe tip and the sample under study. Raster scanning the tip across the surface, through the use of piezoelectric transducers while maintaining a constant tunnelling current, images a surface of constant density of electronic states. The resulting image is a convolution of topographic and electronic properties of the sample surface.

The tunnelling current is exponentially dependent on the tip–sample separation and linearly dependent on the densities of tip and sample electronic states. The applied bias voltage determines which electronic states, on the both sides of the tunnelling junction, are being sampled, and thus allows acquisition of *spatially resolved spectra*. **Figure 1** is a schematic of the tunnelling potential barrier. Adjusting the bias voltage probes different electronic states, allowing the local density of states to be mapped as a function of energy. This is the basis of electronic spectroscopy with the STM.

Scanning Tunnelling Microscope

Experimental Methods

Voltage-Dependent Imaging

One straightforward means to gain spectroscopic information from the STM is to acquire multiple images of

Figure 1 Energy level diagram for the tip–sample tunnelling gap, depicting electrons tunnelling from tip to sample. The local density of states for both the tip and sample as a function of energy is represented graphically.

Figure 2 A composite of two images of the GaAs(110) surface. The orange features obtained at positive sample bias are the Ga atoms, while green features obtained at a negative sample bias are the As atoms. Feenstra RM, unpublished results.

the same area sequentially at different bias voltage, and thus different energies. These images are then overlaid. Each image shows the relative contributions from features at the particular energy relative to the Fermi level defined by the bias voltage (at energies eV , where V is the bias voltage and e is the charge on an electron). Another method is to acquire tunnelling current vs. bias voltage (I - V) characteristics at every imaged point, or at selected locations.

A dramatic example of this technique is the contrast reversal observed for some semiconductor surfaces. When voltage-dependent imaging of GaAs(110) is performed, only the Ga atoms are imaged when electrons are tunnelling into surface states, while the As atoms are imaged when electrons are tunnelling from filled surface states to the tip. **Figure 2** is a superposition of two images of the GaAs(110) surface. The orange image was obtained at positive sample bias, thus imaging the Ga atoms, while the green image was obtained with a negative sample bias, showing the As atoms. The cause of this contrast reversal is charge transfer from the Ga to the more electronegative As atoms, which results in the localization of the lowest lying empty states and highest lying filled states on the Ga and As atoms, respectively.

Voltage-dependent imaging can also be applied to understand bonding of adsorbate molecules to surfaces. **Figure 3** shows a Ni_3 cluster on MoS_2 at a temperature of 4 K, imaged at three different bias voltages. The cluster's contribution to the electronic structure varies dramatically as can be seen at these different energies. At

Figure 3 Three STM images of a Ni_3 cluster adsorbed on a MoS_2 basal plane at 4 K. All three images show a $60 \text{ \AA} \times 60 \text{ \AA}$ area and are plotted as three-dimensional representations with the same aspect ratio and with the same angle of view. The images were acquired with sample biases of: +2 V (upper), +1.4 V (middle), and -2 V (lower). Reproduced with the permission of the American Chemical Society from Kushmerick JG and Weiss PS (1998) *Journal of Physical Chemistry B* 102: 10094–10097.

+2 V sample bias (electrons tunnelling into the empty states on the surface) the Ni_3 cluster appears as a significant protrusion from the MoS_2 surface, indicating that it enhances the local density of empty electronic states at this energy. Similarly, we see that the cluster depletes the local density of filled states at -2 V sample bias (electrons tunnelling from the filled sample electron states to the tip) since the cluster then appears as a depression in the surface. At a sample bias of +1.4 V the cluster is not directly apparent but a diffuse ring $\sim 30 \text{ \AA}$ in diameter surrounding it is imaged. This ring is outside the atomic positions of the Ni_3 cluster imaged at +2 V ($\sim 16 \text{ \AA}$ diameter), and results from a perturbation of the MoS_2 surface electronic structure by the Ni_3 cluster. This ring is believed to be purely electronic in origin with little change in atomic positions of the substrate. Each image shows a different contribution of the Ni_3 cluster to the surface electronic structure, demonstrating how voltage-dependent imaging can measure electronic states as a function of both energy and position.

Voltage-dependent imaging can be a powerful technique but it does have some inherent problems. It is necessary to obtain many images in order to map the surface electronic structure as a function of energy. Thermal drift and piezoelectric creep can make overlay and comparison of successive images difficult. The fact that the constant current images acquired are a

convolution of geometric and electronic effects further complicates the interpretation of observed features. The latter technique of recording complete or selected sets of I - V characteristics, discussed in the next section, overcomes some of these problems.

Local Current-Voltage Measurements

Spectroscopic information over a large energy scale can be obtained by acquiring complete I - V curves at one or many locations. This can be accomplished by releasing feedback control while holding the probe tip steady and measuring the current with respect to applied bias voltage. Spectroscopy with the probe tip held in place allows scanning at both polarities and through zero bias.

Spectra are usually plotted as $(dI/dV)/(I/V)$ vs. V for comparison to other measurements of surface densities of states. This normalizes the spectra, removing the dependence on voltage and the exponential dependence on tip-sample separation. The derivative dI/dV can be numerically calculated, or a lock-in amplifier can be used to measure dI/dV phase sensitively, with a superimposed sinusoidal modulation on the bias voltage.

Synchronizing the feedback blanking and the applied voltage ramp enables acquisition of I - V curves at specified points in an image, thus mapping the energy and position dependence of the surface electronic structure in one image. **Figure 4** shows spectra acquired over Si atoms at three different locations in the unit cell of the Si(111)-(7 × 7) surface reconstruction. The three spectra show different electronic features due to the local bonding and environment of the Si atom probed.

Collection of data for the entire energy region of interest circumvents the need to construct a spectrum from several images. The dynamic signal range plays a role in determining how large an energy range can be scanned. The current goes to zero as the magnitude of the bias voltage decreases. Thus, features at high and low bias voltages can be hard to resolve in a single spectrum (recall that the preferred display of spectra, $(dI/dV)/(I/V)$ vs. V , has tunnelling current in the denominator).

Scanning Tunnelling Spectroscopy

Closely related to voltage-dependent tunnelling is the modulation technique of scanning tunnelling spectroscopy (STS). This technique consists of superimposing a small sinusoidal modulation voltage on the constant DC bias voltage. The modulation frequency is typically chosen to be higher than the cut-off frequency of the feedback loop, resulting in a constant average tunnelling current. If the modulation frequency is too low, the control electronics will attempt to compensate by adjusting the gap spacing. Alternatively, control of the tip height can be released during acquisition of spectra. By measuring the in-phase tunnelling current modulation with a lock-in amplifier, dI/dV can be recorded

simultaneously with the constant current image. Structure in dI/dV as a function of the applied bias voltage can be attributed to structure in the local density of surface states.

Application of STS at constant average tunnelling current suffers from two disadvantages. The first is that the magnitude of the dI/dV signal scales as I/V , and thus becomes progressively small at low bias voltages. The second is that at low bias voltages the tip-sample separation reduces in order to maintain a constant average tunnelling current. If the density of states is too low, the tip will come into contact and damage the surface. This form of STS, like voltage-dependent imaging, requires the acquisition of multiple images to map out electronic structure as a function of energy.

Figure 4 Atom-resolved spectra of the Si(111)-(7 × 7) surface obtained at positions indicated in the upper schematic. Reproduced with permission of the American Institute of Physics from Wolkow R and Avouris PH (1988) *Physical Review Letters* 60: 1049–1052.

Barrier Height Spectroscopy

Lack of direct knowledge of the effective height and width of the tunnelling barrier during spectroscopic measurements makes quantitative understanding of spectra difficult. Properties of the tunnelling barrier can however be investigated, giving information complementary to I - V spectroscopy. Barrier height spectroscopy consists of measuring the dependence of the tunnelling current on the tip-sample separation, at constant bias voltage. What is actually measured is the apparent barrier height, which is defined as

$$\Phi_{\text{ap}} = \left[\frac{1}{1.025} \cdot \frac{d(\ln G_t)}{dz} \right]^2$$

where G_t is the tunnelling conductance. Thus by measuring current as a function of tip-sample separation, G_t and Φ_{ap} can be calculated.

By applying a small modulation to the tip-sample separation (z) at constant bias voltage and constant tunnelling current, a lock-in amplifier can be used to measure dI/dz . The modulation frequency is chosen to be larger than the feedback loop bandwidth but smaller than resonant mechanical frequencies of the microscope. The dI/dz signal measured is directly related to the local surface work function and often provides useful contrast.

Another method of measuring the apparent barrier height is to record the tunnelling current directly as a function of tip-sample separation for a constant bias voltage. The tip-sample separation is reduced while the tunnelling current is measured. Although conceptually simple, there are experimental complications that must be taken into account. As the tip-sample separation becomes very small, the attractive forces between them tend to deform the tip and cause the actual separation to be smaller than expected. In fact, while point contact is typically used as the reference for tip-sample separation, this contact is usually realized with a jump to contact from a small separation. It can also be difficult to maintain a constant bias voltage, as the tip-sample separation becomes very small, since the junction impedance can become comparable to that of the current preamplifier causing a significant decrease in the actual bias voltage. By measuring the voltage across the junction as well as the tunnelling current this problem can be overcome. **Figure 5** shows tunneling current and bias voltage as a function of tip-sample separation for a Au(110) sample and W tip (most probably covered with Au). The dramatic decrease in bias voltage at small tip-sample separations can be seen.

Inelastic Electron Tunnelling Spectroscopy

The majority of the tunnelling current consists of elastically tunnelling electrons. Inelastic pathways in which tunnelling electrons excite transitions can be used for

recording local spectra. For a vibrational transition of a molecule contained in the junction this can occur above the threshold voltage of $|V| = \hbar\omega/e$ (**Figure 6**), where $\hbar\omega$ is the energy of a molecular vibrational transition, and e is the charge of an electron. Inelastic pathways effectively increase the available number of final states for a tunnelling electron, thus producing a kink in the I - V curve at $|V| = \hbar\omega/e$ for each vibrational transition excited. Using a similar modulation technique to that previously described d^2I/dV^2 vs. V can be measured directly with a lock-in amplifier (as the second harmonic

Figure 5 Tunnelling current (I_t), and bias voltage (V_t) during tip approach on Au(110). Reproduced with permission of the American Institute of Physics from Olesen L, et al. (1996) *Physics Review Letters* 76: 1485–1488.

Figure 6 Energy level diagram for tip-sample tunnelling gap depicting both elastic (I_{el}) and inelastic (I_{inel}) tunnelling. Above the threshold voltage $|V| = \hbar\omega/e$ tunnelling electrons can excite a vibrational transition, for molecules in the tunnel junction. The densities of states of both tip and sample have been neglected for clarity.

of the modulation frequency). This has the benefit of transforming the kinks in I - V to peaks and dips in d^2I/dV^2 vs. V , some of which may be assigned to molecular vibrations (of energy eV). Vibrational spectra can be obtained in this fashion for molecules in metal-insulator-metal sandwich tunnel junctions at low temperature. Limiting peak widths of the observable features also requires low temperatures as in tunnel diodes and sandwich tunnel junctions. **Figure 7** shows inelastic electron tunnelling spectra of acetylene (C_2H_2) and perdeuterated acetylene (C_2D_2), adsorbed on Cu(100) at 8 K, and the difference spectrum. The spectrum of acetylene has a peak at 359 meV corresponding to the C=H stretch. This peak is shifted to 267 meV for the C=D stretch in perdeuterated acetylene. Tuning the bias voltage to the energy of the vibrational mode and monitoring d^2I/dV^2 allows vibrational spectroscopic imaging. **Figure 8** demonstrates vibrational spectroscopic imaging of acetylene and perdeuterated acetylene of Cu(100).

Inelastic electron tunnelling spectroscopy with the STM allows unambiguous chemical identification of surface species, as demonstrated above. Electronic spectroscopy is also capable of differentiating between limited sets of adsorbates but does not as a rule enable such determinations. The vibrational spectra of isolated molecules also shed light on the chemical environment and bonding changes of minority surface sites, and their critical role in surface processes, such as chemistry, corrosion, and film growth.

Photon Emission

Electrons tunnelling inelastically between tip and surface can induce photon emission from the tunnel junction. On some surfaces, the inelastic tunnelling is enhanced by exciting surface plasmons, which decay by emitting a

photon. Measuring emitted photons as a function of applied bias voltage yields information analogous to conventional inverse photon emission experiments. Unlike conventional inverse photon emission experiments occupied and unoccupied electronic states can be probed with photon-emission STM by scanning positive or negative bias voltages, respectively. Dispersing the emission with a spectrometer allows the spectral fingerprint of a feature to be measured. The spatial resolution of the STM allows the emission spectrum of isolated molecules to be recorded.

Instrumentation

Microscope

Design considerations for spectroscopy with the STM are the same as for the STM in general. Due to the exponential dependence of tunnelling current on tip-sample separation, vibration isolation is of critical importance. The most demanding of the techniques mentioned above, inelastic electron tunnelling spectroscopy, requires special vibration isolation down to the level of ~ 0.001 Å over a limited bandwidth and operation at extremely low temperatures (ca. 4 K). Various designs for vibration isolation have been implemented, from placing the STM on top of a Viton stack, to mounting the instrument on a pneumatically suspended laser table enclosed in an acoustic isolation chamber. The STM itself should be constructed rigidly so as to yield the highest possible resonance frequencies. Shielding from electronic noise is also important, but is determined primarily by the design of the control electronics as will be discussed below.

Other aspects of the microscope design depend upon the intended experiments. I - V spectra can be obtained in air, if the system to be studied is not air-sensitive. Investigation of isolated adsorbates on metal single crystals requires ultrahigh vacuum, to enable sample preparation, and often cryogenic temperatures, to limit thermally activated diffusion. Cryogenic cooling also reduces thermal drift allowing an area to be studied repeatedly.

Electronics

Low-noise electronics are important to maintain the stability of the probe tip and to avoid coupling of the control electronics to AC voltages powering the electronics or in nearby equipment. Proper shielding and planning can reduce the electronic noise to sufficiently low levels that this is rarely a limiting factor.

Blanking the feedback loop, which is required for many of the spectroscopic techniques discussed, is typically accomplished through the use of a sample-and-hold circuit. In normal operation, the STM maintains a constant tunnelling current by driving the z -piezoelectric transducer with the error signal generated from the

Figure 7 Inelastic electron tunnelling spectra of C_2H_2 (1) C_2D_2 (2) taken with the same STM tip and the difference spectra (1-2). Reproduced with the permission of the American Association for the Advancement of Science from Stipe BC, et al. (1998) *Science* 280: 1732-1735.

(1998) *Science* 280: 1732–1735.

difference of the tunnelling current (converted to a voltage by the preamplifier) and a reference voltage. A sample-and-hold circuit interrupts the input to the feedback control loop and thus maintains a constant voltage to the piezoelectric transducer controlling tip–sample separation. The applied z -piezoelectric voltage, can be held constant for up to several seconds with such a circuit. If longer blanking times are required, the use of a digital feedback blanking circuit can hold the voltage constant indefinitely. In addition, nearly constant drift can be corrected in microscopes where hold times are long compared to drift rates.

Microscope Probe Tip

Since the observed spectral features are a convolution of both the tip and the sample electronic density of states, understanding the role of the microscope probe tip in determining the observed spectra is critical to allowing interpretation of spectral features. A tip with a constant, preferably flat, density of states is typically desirable so that the sample's electronic structure dominates the spectral features observed. Alternatively a probe tip with a single sharp spectral feature can be useful in obtaining spectra.

Semiconductors have greatly varying densities of states and thus contributions from metal probe tips are less prominent. Metal surface state densities vary to a much smaller degree and are thus comparable to those of the tip states, making electronic spectroscopy of metals more complicated. To enable comparison between

spectra obtained at various surface positions it is important that the tip structure, and thus density of states, remains constant between measurements. Rearrangement of the tip apex can greatly affect the observed spectra and thus lead to spurious data interpretation.

Heteroatoms adsorbed to the tip can also play a large role in determining the observed spectra. Many studies have shown that the transfer of an adatom or molecule to the STM tip can affect the observed topography, e.g. yielding atomic resolution on an electronically flat close-packed metal substrate. The spectroscopic effects can be even larger. Special care must be taken when probing semiconductor surfaces. Tip–sample contact resulting in some semiconductor material on the probe tip apex can give rise to odd effects, such as negative differential resistance (NDR). The tunnelling current between tip and sample normally increases with increasing bias voltage. If, however, there is a band gap on both the tip and sample, the tunnelling current can decrease with increasing bias voltage, due to the decrease in overlap of the density of states when the two band gaps are not aligned. **Figure 9** is an I - V curve exhibiting NDR of MoS_2 , with a tungsten tip that came in contact with the surface. By backing away from the surface and field cleaning the tip, I - V curves without NDR are again obtained.

Negative differential resistance can also be observed for surfaces with localized trap states. A tunnelling electron can become localized for long times in these surface states, when they are in resonance with the Fermi level of the tip. Electrons so localized electrostatically

Figure 9 I - V scan of MoS_2 with a tungsten tip demonstrating negative differential resistance caused by the presence of MoS_2 on the tip. Kushmerick JG and Weiss PS, unpublished results.

repel other electrons causing a decrease in tunnelling current, referred to as a coulomb blockade. The voltage at which the NDR occurs is a measure of the energy of the localized trap state.

Other Scanning Probe Microscopes

Atomic Force Microscope (AFM)

It is possible to perform spectroscopy with SPMs other than the STM. The use of metal-coated cantilevers allows spectroscopic measurements with the AFM. The AFM maps surface topography by monitoring the attractive and/or repulsive probe-surface interactions as a surface is scanned by a cantilever. With a metal-coated cantilever, I - V curves can be obtained for surfaces incompatible for STM study, such as metal structures covered with an insulating oxide layer. The insulating film acts as a tunnelling barrier of constant width, allowing spectroscopic measurements analogous to constant-separation I - V scans.

Functionalization of a cantilever by deposition of a molecular film allows the chemical forces between molecules to be probed. The chemical force (bonding) between a functionalized cantilever and surface is measured by monitoring cantilever deflection while the sample approaches, makes contact with, then is drawn back from the probe. The deflection of the cantilever is then converted to a force from the cantilever spring constant. **Figure 10** is a plot of force versus cantilever displacement curves for three combinations of tip and sample functionalization. The hysteresis in the curves is a measure of the adhesive interactions between probe and sample. It can be seen that the strongest adhesion is when both the cantilever and sample are functionalized with the $-\text{COOH}$ (hydrophilic) groups. Functionalization of

Figure 10 Force versus displacement curves recorded between functionalized atomic force microscope cantilever probes and surfaces. The adhesive interactions are strong for like-like interactions (COOH-COOH and $\text{CH}_3\text{-CH}_3$) but weak for interaction between unlike functional groups (COOH-CH_3). Noy A, Frisbie CD and Lieber CM, unpublished results.

the tip and sample with (hydrophobic) $-\text{CH}_3$ groups also yields a strong attractive interaction, but adhesion between $-\text{COOH}$ and $-\text{CH}_3$ is minimal due to their smaller interactions. Such measurements are sometimes called chemical force microscopy.

Near-Field Scanning Optical Microscope (NSOM)

The NSOM also enables localized spectroscopic measurements. This technique circumvents the diffraction-limited resolution of conventional optical microscopy by scanning a light source or collector in close proximity to the surface of interest. A metal-clad optical fibre typically serves as the probe, allowing light to be either emitted or collected from its apex which is free of any metal cladding. Other probes can also be used. By bringing the probe-sample separation into the near-field regime, the spatial resolution achieved is determined by the size of

Figure 11 Fluorescence emission near-field scanning optical microscope image ($1.3\ \mu\text{m} \times 1.3\ \mu\text{m}$) of a photosynthetic membrane fragment. Reproduced with permission of the American Chemical Society from Dunn RC, et al. (1994) *Journal of Physical Chemistry* 98: 3094–3098.

the unclad probe apex and can go well below the far-field limit of $\lambda/2$, where λ is the wavelength of light used. The NSOM can record absorption and fluorescence spectra, as well as measure the refractive index of surface and subsurface species. Spatial resolution of 12 nm has been achieved with visible light. While resolution is lower than that attainable with the STM, the ease of interpretation and familiarity of optical spectra make this technique attractive. Systems particularly suited to study with NSOM include unique biological structures such as the photosynthetic membrane shown in **Figure 11**.

If infrared absorption or Raman scattering is used as the contrast mechanism, vibrational spectra of samples can be obtained. The combination of the nanoscale spatial resolution of a scanned probe with the chemical specificity of vibrational spectroscopy allows *in situ* mapping of chemical functional groups with subwavelength spatial resolution. **Figure 12** is a shear force image of a thin polystyrene film along with a representative near-field spectrum of the aromatic C–H stretch region recorded in the microscope with a 1 second integration time per point.

Also suitable for study are dopants in semiconductors and local structures in semiconductor lasers.

Overview

Spectroscopies with SPMs are being developed rapidly. The ability to study isolated or small structures of adsorbates has allowed incredible insight into the rich chemistry of surfaces, particularly the defining roles that defect-sites play. For example, in terms of imaging, technologies are now available for precise manipulation of material on surfaces and for positioning of specific

atoms at specific locations, as published by Tseng and Li in 2007 (see Further Reading section). The demonstrations of single molecule vibrational spectroscopies with the STM and NSOM have further opened up new avenues for investigation.

The family of scanning probe microscopes (SPMs) have revolutionary imaging capabilities on a range of materials. For example, atomic resolution images of metal and semiconductor surfaces produced by the scanning tunnelling microscope (STM) or images of individual biomolecules in aqueous environments recorded by atomic force microscopy (AFM) are now routine in the literature. Perhaps, less well known, is the even greater potential of these and other probe-based techniques to produce spatially resolved spectroscopic information at the atomic or molecular level. Following a brief introduction to the principal SPMs available, this article will review as comprehensively as possible the wide ranging applications of spectroscopic SPM in semiconductor, material and life sciences.

Methods and Instrumentation

The term SPM encompasses a family of surface-sensitive techniques, each based upon the interrogation at the nanometre level of a specific physical property by a sharp proximal probe. For example the original SPM, the STM measures local conductivity and the AFM local surface hardness. **Figure 1** provides a summary of the operation of the most popular types of SPM. Extensive discussions on the operations of the various forms of SPMs can be found in numerous reviews of the subject. Here we briefly highlight the three SPMs most readily applied to spectroscopic measurements, the STM, the AFM and the near-field scanning optical microscope (NSOM).

STM

It was noted early in the use of STM that the appearance of a surface, particularly at atomic resolution, often changes dramatically with applied sample-tip bias voltage. This phenomenon results since electrons tunnelling between the tip and the surface do so between discrete

electronic states and these states change with applied bias. In the extreme case of changes in tip bias polarity, either occupied (tip positive) or empty states (tip negative) in the sample are responsible for image contrast. Hence, it is possible to 'image' the location of specific bonding and antibonding orbitals and, with care, identify surface species by their electronic signature.

The first type of spectroscopy investigated by STM was current (I) versus gap distance (s). Here the tunnelling current is recorded as the metallic STM probe approaches a sample surface. The local barrier height (ϕ) of the surface can also be estimated from this $I-s$ data using, $\phi = 0.952(d \ln I/ds)^2$ where s is in Å (note that ϕ is a strong function of tip shape, a generally unknown parameter). Electronic structure has also been studied by ramping the tip bias voltage (V) while recording the resultant tunnelling current. This measurement can be carried out at a single point or at each point in a topography scan, hence producing spatially resolved spectroscopic data. Plotting $d \ln I/d \ln V$ versus V has been shown to be proportional to the density of states in the low voltage limit ($\phi > V$).

AFM

Since its inception by Binnig et al. in 1986, AFM has become an important and widespread tool for imaging surface topography with nanometre resolution. AFM is essentially a very sensitive profilometer, measuring surface topography using a sharp stylus, or probe, mounted on a soft spring, or cantilever (**Figure 1**). The ability of AFM to image samples in ambient or aqueous environments is particularly attractive in biomolecular and electrochemical studies.

By exploiting the local nature of an AFM probe and its pico-Newton force sensitivity considerably more information can be extracted from AFM than just surface topography, for example local tribology and force probe-sample separation spectra. During such force probe-sample measurements the probe is moved towards the surface at constant velocity until it is brought into contact with the sample up to a predetermined point of maximum load. The direction of motion is then reversed and the probe is withdrawn from the sample surface. As the probe is withdrawn from the sample the probe may stick to the surface due to interactions between the probe and the sample. The

Figure 1 Schematic representation of the key components of a scanning tunnelling microscope (STM), a near-field scanning optical microscope (NSOM) and an atomic force microscope (AFM). In an STM, an sharp metallic probe is brought into close proximity with a conducting sample. A small bias voltage between probe and sample causes a tunnelling current to flow. This current is recorded as the sample is scanned beneath the probe. In NSOM, the sample is placed in the near-field region of a subwavelength-sized light source. The transmitted or reflected optical signal is used to form an image of the scanning sample. AFM microscopy relies upon the effect of repulsive and attractive forces between the probe and sample to bend a supporting cantilever. The bending of the cantilever, and hence the force, is extracted by monitoring the path of a laser beam reflected from the back of the cantilever.

magnitude of this 'sticking' force and its temporal evolution can reveal details of the type and dynamics of the forces occurring between probe and surface.

NSOM

NSOM represents one of the most promising optical techniques that aims to overcome the Abbé barrier, and yet retain most of traditional optical microscopy's utility. A NSOM typically illuminates a local area of a sample by transmitting laser light through a subwavelength-sized aperture, as defined by the end of a tapered metal-coated optical fibre. An image is then formed by raster-scanning the aperture close to the sample surface and collecting either the transmitted or the reflected light (**Figure 1**). In such a regime, it is the aperture of the NSOM probe that determines the ultimate resolution.

Since NSOM utilizes optically based contrast it has the potential to exploit optical spectroscopies with resolution comparable to the probe dimensions, i.e. tens of nanometres. For example, steady state and time-resolved fluorescence spectroscopy and Raman spectroscopy have been demonstrated with NSOM. Despite some notable successes it is important to note that the combination of the difficulty in the interpretation of NSOM data and the often poor optical efficiency of NSOM probes presently makes the application of NSOM the most challenging form of SPM.

Applications of Spatially Resolved SPM

The breadth of applications of SPM for spectroscopic measurements is considerable. In order to highlight key examples, the discussion is classified by the nature of the

sample investigated, ranging from atomic scale studies on semiconductors and metals to the study of biomolecular interactions.

Semiconductors

The first atomically resolved scanning tunnelling spectroscopy (STS) data were obtained by Hamers et al. (1986) on Si(111)-(7 × 7), showing chemically inequivalent atoms within each unit cell. Since this time many semiconductors have been studied by STS studies carried out under ultrahigh vacuum. For example, dI/dV curves recorded from In atoms adsorbed onto the Si(111)-(7 × 7) surface show that covalent bonding between the In and Si surface states saturates the Si intrinsic metallic states. STS studies of Li on *p*-type Si(001) show strong negative differential resistance and the related existence of thermally activated electron traps. Spatially resolved STS has also distinguished inequivalent sites on a roughened Si(001) surface. Spectra recorded from terraces show bonding and antibonding states at +0.5 V and −0.5 V; however, Si atoms recorded from a step show a marked metallic character. It should be noted that a quantitative analysis of such spectra can be problematic due to the generally unknown nature of the tip's electronic structure and the change in shape of the tunnelling barrier with applied tip-sample voltage bias. Nevertheless, such sensitivity has been very successfully exploited for the study of semiconductor surfaces.

Although many methods exist for the optical characterization of semiconductor surfaces, when high spatial resolution is required, for example with an inhomogeneous surface, new techniques are required. Here NSOM has significant potential and has been employed to map photoluminescence intensity simultaneously with topography on quantum-well structures and hence local carrier density. The data were shown to be consistent with a diffusion-based model and the existence of short-lifetime carriers at the quantum-well boundary. Low-temperature NSOM at 4.2 K has been used to show a vertical dependence of spectral shape in GaAs quantum dots. NSOM has also been employed to acquire Raman spectra from rubidium-doped regions of KTiO_2PO_4 sample, although long acquisition times and very small signal levels have limited progress. Despite this, NSOM Raman has also been successfully employed to map residual stresses in silicon wafers associated with deformation (Figure 2).

Metals

In comparison to semiconductor surfaces, metals display smaller corrugations in their density of states due to very delocalized bonding. Nevertheless, early STM studies revealed relatively high atomic corrugations on Au(111).

Figure 2 (a) Topography image recorded using NSOM showing a scratch on a silicon wafer surface. Inset is an enlargement of the area that was Raman mapped. The scale bar is 1 μm. An array of 26 by 21 spectra were recorded with step sizes of 154 nm and 190 nm in the *X* and *Y* directions, respectively. Each spectrum took 60 s to acquire giving a total image acquisition time of just over 9 h. In (b) the value of centre frequency of the silicon band was extracted and is shown as a function of distance across the scratch; the lateral position of the data points is shown on the topographic cross section (c). Reprinted with permission from Webster S, Batchelder DN, and Smith DA (1998) Submicron resolution measurement of stress in silicon by near-field Raman spectroscopy. *Applied Physics Letters* 72: 1478–1480.

It has since been shown that this ‘super’ resolution results from the nature of the electronic density of states on face-centred cubic metal surfaces.

Elemental-specific contrast on metals using STS has been demonstrated for copper on W(110) and Mo(110) surfaces. Resonant tunnelling via surface and image states provide elemental identification. Theoretical treatment of elemental identification of adsorbates on metals indicates that up to 2 Å peaks should be present in images of electropositive elements on Pt(111) and that 0.35 Å depressions would result from electronegative oxygen atoms.

Low-temperature ultrahigh-vacuum STM has been used to perform atomically localized spectroscopic measurements on single Fe atoms adsorbed onto the Pt(111)

surface. Using dI/dV spectra a resonance was found to occur in the adatom local densities of states that is centred 0.5 eV above the Fermi energy. This feature had a width of approximately 0.6 eV, and occurred only when the tip was within angstroms (laterally) of the centre of an Fe adatom. Following on from this work it was found that Fe adatoms strongly scatter metallic surface state electrons and hence are good building blocks for constructing atomic-scale barriers to confine electrons. 'Quantum corral' barriers constructed by individually positioning Fe adatoms using the STM tip reveal, via STS, discrete resonances inside the corrals, consistent with size quantization (Figure 3).

Superconductors

Cryogenic STS is an ideal tool for studying the electronic nature of superconductors and has produced local dI/dV spectra at the BiO cleavage planes of a bismuth cuprate superconductor at 4.2 K. The spectra confirm a large gap parameter associated with an apparently gapless density of states on the uppermost layer. Spatial variations of the gap parameter on a 100 Å scale were attributed to variations in BiO metallicity with two characteristic dI/dV spectral shapes over regions of metallic and nonmetallic BiO layers. Low-temperature STS has also been employed to probe the local effects of magnetic impurities on superconductivity. Tunnelling spectra obtained near magnetic adsorbates reveal the presence of excitations within the superconductor's energy gap that can be detected over a few atomic diameters around the impurity at the surface. These excitations are locally asymmetric with respect to tunnelling of electrons and holes. A model calculation based on the Bogoliubov-de Gennes equations can be used to understand the details of the local tunnelling spectra.

Polymers

New higher throughput NSOM probes have permitted the recording of Raman spectra from polystyrene spheres labelled with different dyes and adsorbed on silver substrates. No significant differences in near-field and far-field Raman spectra were observed with the NSOM data, clearly demonstrating true chemical identification. Nonresonance Raman spectra of polydiacetylene crystals (Figure 4) demonstrate the feasibility of acquiring spatially resolved Raman spectra despite very low signal levels.

NSOM has also been used to probe the excitonic transitions in J-aggregates of 1,1'-diethyl-2,2'-cyanine iodide grown in poly(vinyl sulfate) thin films. Fluorescence spectra recorded as a function of the NSOM tip position along individual aggregates show only slight variations and are very similar to the bulk aggregate spectrum. The absence of spectral broadening is assigned as evidence for a uniform, well-ordered molecular structure within the aggregates.

Biological Systems

NSOM fluorescence image and spectrographs of recombinant *Escherichia coli* cloned to produce green fluorescence protein (GFP) show a difference in fluorescence distribution within individual bacteria. Fluorescence activity of GFP can thus be used as a convenient indicator of transformation. Improvements in NSOM probe-sample distance control have facilitated the fluorescence imaging of thick biological specimens, such as neurons, astrocytes and mast cells, which also fluoresce in the far-field and hence would normally reduce optical resolution. NSOM has also been used to provide high-resolution information on *in situ* interactions between proteins in biological membranes, in particular human red blood cells invaded by the malaria parasite, *Plasmodium falciparum*. During infection, the parasite expresses proteins that are transported to the cell membrane. Host and parasite proteins were selectively labelled in indirect immunofluorescence antibody assays, and simultaneous NSOM dual-colour excitation fluorescence maps produced.

Karyomes of human metaphase chromosomes are used to detect genetic defects like deletions or translocations, where the chromosomes are treated by the trypsin-Giemsa protocol, to produce a typical banding pattern and imaged by optical microscopy. Because of the diffraction limit in optical microscopy, even the smallest visible band contains around 1 million base pairs. Improved resolution has been demonstrated using fluorescence NSOM on the treated chromosomes compared to conventional light microscopy.

Single Molecule Studies

Spatially resolved STS has been used to characterize the electronic structure of C_{60} molecules on a range of substrates including Au(001), Au(110), Au(111) and Al(111). Due to a lattice mismatch between the overlayer C_{60} and the substrate Au(100) surface, a uniaxial stress is applied resulting in several types of oblique lattices and modified electron charge density around the C_{60} molecules. Charge transfer from the substrate to the molecules and intermolecular bonding under stress were observed in STS data. STS also clearly differentiates inequivalent adsorption sites on Au(111) and Al(111). The STM tip has been used to locally excite single C_{60} molecules to luminesce with an emission spot size of 0.4 nm. Fullerenes have been employed as STM tips, showing improved performance when studying graphite surfaces.

A number of groups have employed NSOM to record fluorescence spectra from single dye molecules. Fluorescence spectra taken in the near-field showed no broadening due to long-range inhomogeneities as are apparent in far-field spectra. Using picosecond light pulses, time-resolved near-field fluorescence images of

Figure 3 Perspective views of a 60 atom Fe ring recorded at tunnelling current of 1 nA and tip bias voltages of (a) 10 mV and (b) -10 mV. The quantum interference patterns inside the ring change with energy. The energy dependence of the lowest density of states at the centre of the ring is illustrated by the dI/dV spectra in (c). The sharp peaks in the spectra indicate sharp resonances in the lowest density of states. These data match theoretical results based upon the particle-in-a-box model very closely. single sulforhodamine 101 dye molecules and rhodamine 6G have been recorded. Since metal surfaces near radiating dipoles influence fluorescence lifetimes, the fluorescence decay of single molecules is dependent on the relative position of the tip and the molecule. Polarization-sensitive NSOM has been used to resolve mesoscopic spectral inhomogeneities in small crystals of the dye 1,1-diethyl-2,2-cyanine iodide, where the crystals showed strong absorption perpendicular to their long axis and no absorption in the two orthogonal directions.

The sensitivity of fluorescence resonance energy transfer (FRET) has been extended to the single-molecule level by measuring energy transfer between single donor and acceptor fluorophores linked by a short DNA molecule using NSOM. Dual colour images and emission spectra combined with photodestruction dynamics have been used to determine the presence and efficiency of energy transfer. In contrast to ensemble measurements,

Figure 5 A spatially resolved force adhesion map recorded using an AFM probe coated in biotin on a 90% biotin-blocked streptavidin surface. Biotin–streptavidin are a ligand–receptor pair with very high affinity ($10^{15}\ \text{M}^{-1}$) often employed as a model system for molecular recognition studies. The contrast on the image corresponds to the amount of adhesion felt by the probe at the surface. Light areas represent high levels. If the biotin-coated probe contacts the surface in a region where free binding sites exist (i.e. streptavidin unblocked by free biotin) then adhesion based on the biotin–streptavidin specific molecular interaction would be expected. Position X in the image corresponds to an area of adhesion and Y a typical area of no interaction. Hence, X marks the spot of an open streptavidin binding pocket. Reproduced with permission of Gordon and Breach Publishers from Roberts CJ, Allen S, Chen X, Davies MC, Tendler SJB, and Williams PM (1998) Measurement of intermolecular forces using force microscopy: Breaking individual molecular bonds. *Nanobiology* 4: 163–175.

dynamic events on a molecular scale are observable in single-pair FRET measurements because they are not cancelled out by random averaging.

The ability of AFM to directly measure discrete intermolecular forces as low as 10 pN was high-lighted as long ago as 1993. Since then, a number of groups have exploited this ability, using AFM to determine the forces required to separate individual receptor–ligand molecules including avidin–biotin, cell adhesion proteoglycans, antibody–antigen and hydrogen bonding between nucleotide bases. In addition, the potential for mapping surface groups by their functionality using AFM has been exploited to spatially locate the adhesive and frictional interactions between hydrophobic and hydrophilic organic monolayers and biotin–streptavidin (see **Figure 5**).

Molecular dynamics has been used to model the disruption of biotin–streptavidin as it occurs in force adhesion experiments and to relate these forces to molecular structure and conformation. The force is calculated from the steepest slope in the free energy profile along the unbinding pathway. Interestingly the calculated rupture forces show a similar spread in values as is found in experimental data, suggesting that this spread is due to

heterogeneity in the reaction pathway of biotin-streptavidin.

AFM has also been used to measure inter- and intra-chain forces in DNA nucleotides. The interaction forces between complementary 20 base pair lengths of single-stranded oligonucleotides ((ACTG)₅ and (CAGT)₅) and the forces required to stretch and break polydisperse homopolymers of inosine were measured. AFM has also been employed to study the interaction between d(T)₂₀ (dT = 2'-deoxyribosylthymine) and poly(dA) oligonucleotides (dA = 2'-deoxyribosyladenine). As before, rupture forces after binding were measured; however, the dependence of the rupture force with time of contact between the probe and sample was also observed. After 30 s contact, only low adhesion was observed. A maximum probe sample adhesion was observed after 2 min. This incubation-time dependence was interpreted as slow reorientation of partially hybridized oligonucleotide strands into more stable structures and was suggested as a means of studying double-helix annealing processes.

Single-molecule force spectroscopy on dextran filaments linked to a gold surface has been carried out using AFM by vertical stretching, the applied force being recorded as a function of the elongation. At low forces the entropic deformation of dextran dominates and can be

described by the Langevin function with a 6 Å Kuhn length. At elevated forces the strand elongation was governed by the twist of bond angles. At higher forces the dextran filaments underwent a distinct reversible conformational change. This ability to stretch and relax long-chain molecules has also been exploited to unfold individual domains of the giant sarcomeric protein of striated muscle, titin (**Figure 6**). At large extensions, the restoring force exhibited a sawtooth-like pattern. Measurements on recombinant titin immunoglobulin segments of two different lengths exhibited the same pattern and allowed the discontinuities to be attributed to the unfolding of individual immunoglobulin-like domains. The forces required to unfold individual domains ranged from 150 to 300 pN and depended on the pulling speed. Upon relaxation, refolding of immunoglobulin domains was observed.

Future Trends

The resolution and adaptability of scanning probe techniques are increasingly being exploited to carry out spectroscopy measurements, particularly for electronic and optical surface properties. In addition, new variants

Figure 6 Three typical force extension curves obtained by stretching titin molecules. The curves show periodic structure on the retract portion of the data consistent with the unfolding of individual titin domains. of traditional scanning probe spectroscopic methods continue to be developed. For example, STM spectroscopy performed with magnetic probe tips has yielded new information about the spin-resolved nanoelectronic properties of magnetic nanostructures. Also, an adaption of STM to allow the probing of surface acoustic waves is proposed that reaches submicrometre resolution for the quantitative evaluation of elastic constants and studies of nanoscale structures. In AFM, measuring the oscillation amplitude of the probing AFM tip and phase-shift between the cantilever response as a function of the tip-sample distance allows the analyses of the dynamic interaction of the AFM tip with the sample surface. This has been termed dynamic force spectroscopy and has been proposed as a new method of rapidly mapping probe-sample interactions. Advances in NSOM spectroscopic applications are presently centred on improving the optical efficiency of the probe, either through more precise control of fibre-optic probe geometry or through the development of semiconductor-based tips not dissimilar to those in use in AFM.

Other SPM technologies for specific applications are also being developed. For example, magnetic resonance effects have been studied using modified AFMs. The sample is mounted on an AFM cantilever in a magnetic field gradient and exposed to a radiofrequency field which drives the spins into precession. The resultant periodic force is sensed in the normal way from the flexure of the AFM lever. This technique has also been extended to spatially map magnetic resonance data and to detect NMR effects. These data exemplify the reason for the continued rapid growth in SPM applications. The adaptability of the technique to address problems from a range of scientific disciplines and its ability to operate under conditions of vacuum to liquid from 4 K to 1000 K will ensure this pace of SPM advancement continues for the foreseeable future.

M_{tip}	mass of vibrating tip assembly
M_{ts}	matrix element connecting tip and sample states in STM
r_0	centre of curvature of STM tip
R	radius of curvature
V	potential energy of electron
W_{ts}	transition rate between tip and sample states
κ	decay constant for electron wavefunctions ψ
σ	differential conductance
Φ	electrostatic potential
ω	angular frequency of vibration
Ω	normalization volume for tip wavefunction in the Tersoff–Hamann model

Introduction

The three most important scanning probe techniques are

- Scanning tunnelling microscopy (STM);
- Scanning force microscopy (SFM), also known as atomic force microscopy, (AFM);
- Scanning near-field optical microscopy (SNOM).

The three methods give different types of information and require correspondingly different theoretical treatments. STM probes the electronic states of a surface; SFM probes the force (or force gradient) between a tip and a surface; while SNOM probes the electromagnetic field near a surface. In addition, magnetic force microscopy (MFM) is now a recent addition to the range of techniques and is covered by a separate article in this encyclopedia.

However, all these techniques share several common features. First, they measure local, not average, surface properties. Any theory must therefore include the local surface properties if it is to be useful. Second, they all lack a simple *inversion theorem*: in no case is it possible to

infer directly physical properties of the system from the scanning probe results. Interpretation therefore has to proceed by an indirect ‘interpretation cycle’:

1. Build a model of the relevant local features (e.g. structure, excitations) of the system under study;
2. Develop a theory of the scanning probe experiment concerned;
3. Combine (1) and (2) to determine the predicted experimental signal from the model adopted;
4. Alter the model if the predictions and the experiment do not match.

In this article we shall examine what type of model of the physical system under study is appropriate under item (1) of the ‘interpretation cycle’ for each technique, and how a suitable theory of the experiment can be constructed for item (2).

The Scanning Tunnelling Microscope: Electronic Spectroscopy

General Considerations

The fundamental physical process in STM is the tunnelling of electrons between the tip and the sample under study, through the barrier formed by the vacuum between them (see **Figure 1**). The ‘height’ of this barrier in energy is approximately equal to the work functions of the tip or sample material. In the simplest possible one-dimensional model, we assume that the electron potential energy V takes a constant value V_0 through the tunnelling

Figure 1 Schematic diagram of an STM junction at zero bias, illustrating the meaning of the symbols defined in the text.

gap; the barrier height is therefore $(V_0 - E)$ where E is the electron energy. The electron wavefunctions then decay in the vacuum as $\exp(-\kappa z)$, where z is the coordinate normal to the surface and

$$\frac{\hbar^2 \kappa^2}{2m_e} = (V_0 - E) \quad [1]$$

If $V_0 - E$ is 5 eV = 8.01×10^{-19} J then $\kappa = 1.15 \times 10^{10} \text{ m}^{-1}$

Tunnelling can occur from tip to sample and from sample to tip. If no bias is applied to the system (i.e. if the electrochemical potentials of the electrons in tip and sample far from the junction are equal), the rates of tunnelling in opposite directions are equal, and no net current flows. (Note that if the tip and sample have different work functions, a finite charge transfer will occur at zero bias to establish a dipole layer at the surfaces, and hence an electric field in the vacuum gap; it is the potential difference arising from this field which equalizes the electrochemical potential in the two materials.)

Suppose now that a finite bias potential $\Delta\Phi$ is applied to the system (see **Figure 2**), of a sign which raises the electrochemical potential for electrons on the left of the junction by $|e|\Delta\Phi$ relative to those on the right. Over a range of energies, electrons are now more likely to tunnel from left to right than viceversa, and a net current flows from right to left. If the difference in chemical potentials is small so that current is dominated by electrons with a single energy E , we can use the fact that the current is proportional to the tunnelling probability and hence to the absolute square of the wavefunction to deduce that it will vary with the tip-sample separation d as $\exp(-2\kappa d)$, with κ given by eqn [1]. Taking the value of κ we estimated earlier, we obtain the often-quoted rule of thumb that the tunnel current should reduce by roughly a factor of ten whenever the tunnel gap is increased by $1 \text{ \AA} = 10^{-10} \text{ m}$.

This is an approximate theory of the tunnelling process, but it says nothing about the contrast to be expected when the STM tip is moved across the surface. A better

theory must take account of the atomistic structure of the tip and the surface, as well as a better theory of the tunnelling between them. In doing this, it is important to realize that the energy of the tunnelling electrons being used to probe the system is very similar to the energy of electrons in the bonding orbitals holding the atoms together. There is therefore a very close relationship between the tunnelling process, the electronic structure, and the atomic (or chemical) structure of the system.

Step (1) of the 'interpretation cycle' for STM must therefore involve a model of the atomic and electronic structure of the surface, including any adsorbates or surface defects. In practice this is most often obtained numerically using density-functional theory, in which the total energy of the electrons in the system is calculated from the electronic charge density, rather than from the full many-electron wavefunction. The Hartree-Fock method, which employs an approximate form for the many-electron wavefunction which neglects the correlations between the motions of the electrons, is also used. Such calculations are now relatively standard, and many can be found in the literature for surfaces of different types. Step (2) must involve a three-dimensional theory of electron tunnelling between the surface (represented in this way) and the tip; we now turn to this more difficult step.

Perturbation Theory

The interpretation of many spectroscopies (for example, optical spectroscopy) proceeds by the identification of a well-defined 'perturbation' which is applied to the system when the experiment is performed. This is both convenient (because the response of the system to the perturbation is not too difficult to evaluate in terms of the matrix elements of the perturbation) and conceptually useful (because it allows a clear separation between the 'system' and the 'probe').

This is not straightforward in STM. There are two reasons: (i) the tip and the sample may be very close, and hence strongly coupled together, and (ii) even when this is not the case, there are mathematical difficulties in separating the Hamiltonian into parts describing a non-interacting tip and sample, because the kinetic energy operator for the electrons appears in both parts. Nevertheless problem (ii) has been solved, and it has been shown that a sensible perturbation theory can be constructed in which the appropriate matrix element is that of the electron current density operator, evaluated over a surface S separating the tip and the sample (see **Figure 3**). We write

$$M_{ts} = \frac{\hbar^2}{2im_e} \int_S d^2r [\psi_t \nabla \psi_s - \psi_s \nabla \psi_t] \quad [2]$$

Figure 2 Schematic diagram of an STM junction at finite bias.

Figure 3 The important quantities in the Tersoff–Hamann model of STM. The matrix element is evaluated on the surface S ; the conductance is proportional to the sample density of states at the tip centre of curvature r_0 .

where ψ_t is a one-electron state of the tip (in the absence of the sample) and ψ_s is a state of the sample (in the absence of the tip). Note that in order to derive this result, one has to assume that *both* states are valid solutions of the Schrödinger equation in the neighbourhood of the surface S ; this implies that the potential for electrons at S must be equal to the vacuum potential. The transition rate for electrons from state t to state s (or vice versa) can then be written

$$W_{ts} = \frac{2\pi}{\hbar} |M_{ts}|^2 \delta(E_t - E_s) \quad [3]$$

and the total current from tip to sample as

$$I = \sum_{ts} \frac{2\pi}{\hbar} |M_{ts}|^2 \delta(E_t - E_s) f_t(E_t) [1 - f_s(E_s)] \quad [4]$$

where $f_t(E)$ and $f_s(E)$ are the occupation probabilities for electron states with energy E in the tip and the sample respectively.

The most commonly used model in interpreting STM data is the Tersoff–Hamann model, in which the analysis is carried a step further. It is assumed that the tip wavefunction is an s -wave, and decays into the vacuum as

$$\psi_t(\mathbf{r}) = \Omega^{-1/2} \kappa R \exp(\kappa R) \frac{\exp(-\kappa |\mathbf{r} - \mathbf{r}_0|)}{\kappa |\mathbf{r} - \mathbf{r}_0|} \quad [5]$$

where Ω is a normalization volume, r_0 is the centre of the curvature of the tip, R is the radius of curvature, and κ is as defined earlier. In this special case the integral in eqn [2] can be evaluated exactly (under the assumption that ψ_s obeys the free-space Schrödinger equation), and one finds in the limit of small bias that the differential

conductance σ of the STM is

$$\sigma = \frac{32\pi^3}{\hbar} e^2 N_t(E_F) R^2 \kappa^{-4} \exp(2\kappa R) \sum_s |\psi_s(r_0)|^2 \delta(E_s - E_F) \quad [6]$$

Here $N_t(E_F)$ is the total tip density of states at the Fermi energy. This is a very simple and important result; it tells us that the tunnelling conductance measures the sample density of states at the Fermi energy, evaluated at the centre of curvature of the tip (i.e. some distance outside the sample surface). This is relatively straightforward to calculate, and easy to interpret in simple chemical terms. The model disregards all details of the tip; they are absorbed into the values of the constants R and Ω . The (usually unknown) structure of the end of the tip can therefore be disregarded, at the cost of sacrificing any information about the absolute value of the conductance. It is largely because of these advantages that the Tersoff–Hamann model is so popular.

The approximations leading to eqn [6] are valid only if there is no electric field in the vacuum. Nevertheless, the Tersoff–Hamann model is often used to interpret images taken at finite bias voltage $\Delta\Phi$, or even data from the ‘spectroscopic’ mode of the STM in which the tip position is held fixed and the bias varied. The density of states involved in eqn [6] is projected onto a ‘window’ of energies $\Delta E = e\Delta\Phi$, rather than onto a single energy. There is no theoretical justification for this, as the true states of the system are bound to be modified by the addition of such a bias voltage, but it has proved useful as a way of qualitatively rationalizing STM data provided the bias is not too large.

It is possible to extend perturbation theory beyond the Tersoff–Hamann model, for example by including tunnelling to or from states of non-zero angular momentum on the tip, or by using states explicitly calculated from a particular atomistic model to find the matrix element in eqn [2]. However, both these approaches require additional information about the geometry of the tip and the electronic states it supports. This is generally not available from experiment, as a tip will be modified by the forces acting in the course of the experiment (as discussed in more detail below); even if the tip is well characterized before use (for example, by electron microscopy or field-ion microscopy), this information will become out-of-date once the experiment starts.

Another extension of this type of perturbation theory is to the case where there is some additional electronic order in the tip or the sample – for example, magnetic or superconducting order. In the case of magnetic order one is led to consider separate currents of spin-up and spin-down electrons, proportional to the spin-resolved components of the density of states. For a superconductor, the

tunnel current depends on the quasiparticle density of states.

Beyond Perturbation Theory

Perturbation theory of this kind leads to an appealing picture of STM. Nevertheless it is not always justified; here we list some of the reasons why it may break down.

- A substantial redistribution of charge and potential takes place, so the effective one-electron Schrödinger equation is altered. This effect has been predicted theoretically when the tip-sample separation drops below about 3 Å; it tends to result in a lowering of the potential energy for an electron in the vacuum and a collapse of the tunnelling barrier.
- The electron tunnelling probability between tip and sample is not small. In practice this occurs only when the electron transport is no longer dominated by tunnelling – either because a physical contact or *nanojunction* has been formed between the two, or because the tunnel barrier has collapsed completely (see above). The signature of this state of affairs is that the STM conductance becomes of the order of the quantum of conductance, e^2/h .
- Although small, the tunnelling matrix element through the vacuum is not the smallest energy scale in the problem. This can occur when, for example, a highly insulating molecule is adsorbed on a surface; tunnelling through the molecule can then be just as difficult as tunnelling through the vacuum, so it is not appropriate to treat the vacuum tunnelling as a perturbation.

For all these problems, the theoretical cure is the same: one must perform a single coupled calculation for the electron states in the whole system (tip plus adsorbate – if any – plus sample) under a non-zero bias, allowing a current to flow.

However, this has proved to be very difficult without additional simplifications. In the elastic scattering quantum chemistry (ESQC) method developed by Joachim and Sautet, there is no self-consistency in the Hamiltonian for the electrons and only a relatively small basis set, giving very limited flexibility to the electron wavefunctions. In another approach, pioneered by the group of Tsukada, a more detailed numerical representation of the wavefunction is adopted: the wavefunctions are calculated on a mesh of points and full self-consistency is achieved between the wavefunctions and the electronic potential. The simplification in this case is that the wavefunctions far from the tunnel junction are those of a fictitious ‘jellium’ in which the positive charge of the nuclei is smeared out into a uniform background. In yet a third approach the conductance is calculated in a non-

perturbation manner between two localized states, rather than between the true bulk states of the tip and sample.

Other Factors

There are also other factors that are known to be important in STM. One of these is the mechanical interaction between the tip and the sample; the forces that arise can distort the tip, with the result that the displacement of the tip apex is not the same as that recorded from the piezoelectric actuators controlling the tip (see **Figure 4a**). This effect was revealed by careful measurements of the *corrugation* of the STM image of adsorbates on metals as a function of the conductance.

A second effect is that of the tip electric field. This can be very large: fields above 10^9 V m^{-1} can be obtained when a potential difference of a few volts is dropped over a narrow tunnelling gap. This can have two results: first it distorts the atomic structure of the surface, causing

Figure 4 Two physical phenomena which alter STM images from those predicted by simple theory: (a) Tip-sample forces distort the actual change in separation from that measured by the piezoelectric transducers. (b) Electric fields from the tip cause motion of surface atoms and distortion of surface electron states.

movements of a few tenths of an angstrom in the surface atoms, and second it distorts the electronic structure, changing the tunnelling probability at different points on the surface (see **Figure 4b**). These effects have been shown to be important in images of the Si(001) surface.

A third complicating effect is the inelastic scattering of electrons from other excitations during tunnelling. These other excitations may be electronic; the most important example is surface plasmons, which may be found in either the tip or the sample. Scattering from surface plasmons produces electromagnetic disturbances near the tunnel gap which can result in the emission of electromagnetic radiation from the STM. The frequency distribution of the emitted light is then characteristic of the surface plasmon spectrum. The distortion of the surface plasmons can also have other, more subtle, effects since it determines whether or not the electron experiences the effect of the 'image interaction' outside a surface. This can in turn have a large effect on the electron potential and the tunnelling current.

Alternatively, the scattering excitations may be atomic vibrations. These may result in phonon-assisted sidebands around resonant tunnelling peaks, corresponding to the absorption or emission of phonons. In extreme cases the transfer of electronic energy to atomic motion may produce atom transfer between tip and sample, or even desorption; this is a form of DIET (desorption induced by electronic transitions) and may be used to break bonds selectively on surfaces.

The Scanning Force Microscope: Force Spectroscopy

In order to interpret these experiments one needs to bear in mind the different types of forces that can act between the tip and the sample.

- At large distances the force most commonly present is the Van der Waals force. Between two atoms the Van der Waals force energy decays with separation z according to the well-known z^{-7} law, but for a sphere above a planar surface (one simple model for the tip-surface system) the decay is only as z^{-2} . This relatively slow fall-off tells us that in SFM, unlike STM, the large-scale structure of the tip is important.
- If the sample is an insulator, it may be locally charged. The interaction between these local 'patch charges' and the tip also decays like a power law in the tip-sample separation. The patch charges are difficult to control; the highest-resolution SFM results are generally obtained on conducting samples.
- At smaller distances (of the order of 3–5 Å separation) local interactions between the closest atoms of the tip and sample start to become important. These include the onset of covalent bonding, and local electrostatic forces.
- As the tip-sample separation drops below the sum of the atomic radii of the atoms, the Pauli exclusion principle raises the energy of the overlapping electron distributions, producing a repulsive force. If the tip and sample are forced together beyond this point, atomic deformations (first elastic, then plastic) occur.

Models for the Forces

Of these interactions, the Van der Waals attraction and the Pauli repulsion are universal; the presence of the others depends on the nature of the material. The combination of Van der Waals and Pauli interactions is often captured by the simple '6-12' Lennard-Jones interatomic potential

$$V(r) = \epsilon \left[\left(\frac{r}{\sigma} \right)^{-12} - \left(\frac{r}{\sigma} \right)^{-6} \right] \quad [7]$$

in which the attractive r^{-6} term represents the Van der Waals force and the repulsive r^{-12} term the Pauli force. Simulations of generic interatomic interactions are often performed using this potential, although it cannot be expected to be realistic for anything other than interactions between the simplest rare-gas solids. More realistic calculations include approximate forms for the electrostatic and covalent interactions between the atoms, or (better still) find these forces directly from the electronic structure of the materials involved.

High-Resolution SFM Operation

With this in mind, let us examine the most common modes of SFM operation when high-resolution information about the surface is required.

- **Non-contact mode.** In this mode the tip is kept at a distance from the sample in the attractive part of the force-distance curve; usually it is then scanned across the sample, and the tip-sample distance adjusted to keep the cantilever displacement (and hence the force) constant. This procedure keeps the tip in the region where the tip-sample force is (relatively) well understood, but with the price that the force is determined by the cumulative effect of a large number of atoms – hence the resolution of individual atomic-scale features is seldom possible.
- **Contact mode.** Here, by contrast, the tip is allowed to penetrate into the repulsive regime of **Figure 5**. This has the advantage that one expects a large component of the force to be determined by a relatively small number of atoms near the tip apex, but the disadvantage that the force becomes dependent on complex atomic processes involving the irreversible deformation of the tip-sample junction. Images with apparent atomic resolution can be seen in contact mode on simple crystalline materials such as alkali

Figure 5 Schematic force–distance curve for an SFM experiment. On approach, the tip jumps from point a to point b; on retraction, it jumps from c to d. The dotted lines have a slope equal to the cantilever force constant k_{cant} .

halides, but the conclusion of careful simulations is that the atomic-scale features are not, in fact, correlated with the positions of atoms in the surface. This theoretical conclusion is reinforced by the failure to resolve atomic defects (known to be present on the surface) in experiments.

One might think that a technique intermediate between contact and non-contact modes could be devised simply by bringing the tip close to the surface, but not in contact with it. In fact this is very difficult because of the ‘jump-to-contact’ phenomenon: a static tip held above a surface by an SFM cantilever with a given force constant k_{cant} can be stable only as long as the force gradient from the tip–sample interaction is less than k_{cant} (see **Figure 5**). The force gradient of a Van der Waals interaction between a tip and a flat surface diverges as the separation between them is reduced, so this condition is always violated and the tip snaps into contact with the sample. If the tip is pulled off the surface, a similar jump out of contact occurs (although between different values of tip–sample separation).

Since a very interesting range of tip–surface separations is rendered unavailable by the jump to contact, it would be desirable to eliminate it. To date, this has been done in two ways. First, a dynamical approach is used: the cantilever is vibrated above the surface with an amplitude of several hundred angstroms, in such a way that its point of closest approach is only a few angstroms from the surface. The difference from before is that the tip is accelerating rapidly away from the surface as it approaches; this suppresses the jump to contact. One way of expressing this is to say that the effective cantilever force constant is increased from k_{cant} to $k_{\text{cant}} + M_{\text{tip}}\omega^2$, where M_{tip} is the total mass of the vibrating tip and ω is the angular

frequency of vibration. The tip is usually scanned while keeping the vibrational period constant; this corresponds approximately to a scan of constant force gradient. Atomic resolution has been obtained using this technique, initially on the Si(111)- 7×7 surface but now also on others. It seems this resolution can be understood in terms of the interaction between the tip and the surface near the point of closest approach, but the theory is complicated because the vibration of the tip samples all the different regions of the potential surface described above during a cycle, so a unified model containing all of them must be used.

A second approach is to control the force on the tip directly, generally by means of a small magnet mounted on the back. This removes the need to model a complicated tip oscillation, but imposes stringent demands on the response and stability of the electronics controlling the force. Direct measurements of tip–sample potential curves have now been reported using this technique, but comparison with theory is still in its infancy.

Measurements of Elastic Properties

If local but not ultra-high-resolution measurements are required to probe the elastic properties of a hard material, there are advantages in using high-frequency measurements.

The Scanning Near-Field Optical Microscope-Optical Spectroscopy

The theory of scanning near-field optical microscopy is somewhat similar to that of STM, with the transport of light (or photons) replacing the transport of electrical current (electrons). Instead of the Schrödinger equation, the Maxwell equations for the electromagnetic field must be solved near the tip and the sample, taking into account the local electromagnetic properties of each medium. In some respects this is easier, because (in the absence of non-linear media) the Maxwell equations are truly linear and no self-consistency (of the type needed between effective one-electron wavefunctions and the potential) is needed. Also, since the characteristic wavelengths and decay lengths for optical photons are much larger than atomic dimensions, a continuum treatment of the tip and sample materials is almost always sufficient. On the other hand, the Maxwell equations require treatment of two coupled vector fields.

As in the STM case, the equations must in practice be solved numerically. Perturbation theory is seldom employed, and most calculations make a direct solution for the optical modes at a fixed frequency, either by a transfer matrix approach, or by using the Dyson equation to obtain the solution from that of an exactly soluble system (for example, free space).

Conclusions

STM appears to be the most subtle of the scanning probe methods, relying as it does on quantum-mechanical tunnelling. In fact the theory for this technique is the best developed of all the scanning probe family, but much progress remains to be made in accounting correctly for the nature of the tip and for tip-sample interactions. The theory of near-field optical microscopy is similar in spirit, and in some ways more straightforward. The understanding of SFM data is very incomplete, particularly for experiments with resolution on the atomic scale.

Symbols

$E(t)$	electric field at time t
$g^{(1)}(\tau)$	electric field autocorrelation function
$g^{(2)}(\tau)$	intensity autocorrelation function
I_0, I	intensity of incident and scattered light respectively
k_0, k_s	incident and scattered wave vector respectively
n_0, n	refractive index of the medium and of the particle respectively
Q	scattering vector
r	particle radius
R_g	radius of gyration
T	temperature (K)
η	viscosity coefficient
θ	scattering angle
λ	wavelength of incident light
τ	time delay
ω_m	weighting factor.

The scattering of radiation has been used for many years as a noninvasive technique for the determination of particle sizes in suspension and in aerosols. Two fundamentally different experimental approaches are used. In the first approach, fluctuations in the scattered light intensity arising from the diffusive motion of the particles are monitored and analysed by autocorrelation, a procedure that yields the intensity autocorrelation function, a function that corresponds to the Fourier transform of the frequency spectrum. The intensity fluctuation approach, when applied to light scattering, has been given a wide variety of names, including quasi-elastic light scattering (QELS), intensity fluctuation spectroscopy (IFS), photon correlation spectroscopy (PCS) and the currently favoured dynamic light scattering (DLS). Diffusing wave spectroscopy (DWS) is a special type of DLS technique which provides estimates of particle sizes in concentrated, nearly opaque, suspensions. The second approach involves the measurement of the intensity of light, X-rays or neutrons scattered by the particles as a function of the scattering angle. Depending on the source of radiation these are named static light scattering (SLS), small angle X-ray scattering (SAXS) and small angle neutron scattering (SANS).

When the scattering particles are small, monodisperse and spherical, size information can be obtained from either SLS or DLS data by fitting to relatively simple mathematical expressions. Generally, however, the particles are polydisperse (i.e. characterized by a size distribution) and sometimes they can be multimodal, and/or nonspherical. These properties of the sample can severely complicate the analysis and recovery of size information can require the use of relatively complex and indirect data analysis methods. This is because the direct analysis falls into a class of mathematical operations known as 'ill conditioned' transforms that are unstable and severely affected by truncation errors and noisy data. Much of the more recent work in light scattering has centred on finding analysis procedures that minimize these problems. The presence of polydispersity introduces a further consideration. Since the amount of light scattered by a particle is proportional to r^n , where r is the particle radius and n can be as large as 6, there is the consequence that the larger particles of a distribution can scatter considerably more light than the smaller ones. This leads to z -average particle sizes and intensity weighted size distributions in DLS. Conversion of these to number averaged quantities, such as those obtained by analysis of electron microscopic images, requires knowledge of the particle's scattering factor or structure factor and its incorporation into the analysis. These factors can be very simple for very small uniform spheres and approach unity for point particles. When particular criteria are satisfied, approximately when particle diameters are significantly smaller than a wavelength, Rayleigh–Gans–Debye scattering factors can be used. However, once the particle's diameter is of the same order of magnitude or larger than the wavelength then Mie theory must be used to compute scattering factors. To date, Mie factors can be easily computed only for spherical or coated spherical systems.

Basic Physics of Elastic Scattering

The Scattering Vector

During elastic scattering processes, the incident radiation is redirected at all scattering angles as a result of its encounter with the scatterers. By suitable use of pinholes or slits the light scattered at a particular angle, θ , from

the main beam can be detected and analysed (see **Figure 1**). The momentum transfer, which results from such a process, is defined as the vector difference between the incident wave vector, k_0 , and the scattered wave vector k_s . This vector difference, called the scattering vector (Q), has a magnitude that can be obtained from the geometry of the scattering arrangement. That is,

$$|Q| = \frac{4\pi n_0}{\lambda} \sin(\theta/2) \quad [1]$$

where n_0 is the refractive index of the medium surrounding the particles and λ is the wavelength (in a vacuum) of the incident light. It is clear from eqn [1] that Q has the dimensions of an inverse length. Indeed, Q^{-1} sets the length scale which will be probed by the light scattered at angle θ . At low angles, Q^{-1} is large and light scattered in this direction will contain information only on the gross dynamic and structural properties of the particles, whereas light scattered at a high angle contains this information at a finer scale and might, for example, carry information on the internal structure of the particle. **Figure 2** shows a comparison of scattering techniques, and their respective particle sizing ranges. DLS has

Figure 1 The scattering geometry.

Figure 2 Particle sizing ranges for different scattering instruments. DLS: dynamic light scattering, SANS: small-angle neutron scattering, SLS: static light scattering, SAXS: small-angle X-ray scattering, FS: Fraunhofer scattering.

a greater range than other scattering techniques because it is concerned with the distance ($2\pi/Q$) that a particle diffuses before dephasing of the scattered light occurs. Note also that due to the relatively short wavelengths of X-rays and neutrons (typically 0.1 to 1 nm as compared with visible light, 400 to 700 nm), Q^{-1} is appropriate for particle sizing only when θ is very small. As a result, only small angle X-ray or neutron spectrometers are of interest here.

Dynamic Light Scattering

DLS is an established technique for measuring the average size and the size distribution of particles in a suspension. The technique has advantages of being relatively fast, noninvasive, and requires minimal sample preparation (as compared with electron microscopy for example). But it does require low particle concentration. As well, dynamic light scattering results are often open to misinterpretation if one is unaware of the optical properties of the sample and the method of data analysis. The following discussion reviews some of the basic concepts of dynamic light scattering and outlines some of the pitfalls which are often encountered in data interpretation. A modification of DLS is DWS, which can be used to obtain approximate size information at high particle concentrations and is described later.

All DLS spectrometers use a laser as a source of coherent light. This means that all the light incident on the sample is in phase. At any instant the scattering particles will have a particular set of positions within the scattering volume. Because of these positions, the relative phases of the electric fields of the scattered wavelets will differ at the detector due to the differing optical path-lengths that they must travel. The instantaneous electric field at the detector is the superposition of the fields due to all the scattered wavelets and will, at time t , have a value $E(t)$. At the time, $t + \tau$, which is a very small delay time, τ , later than t , the particles, which are diffusing, will have new positions that are slightly removed from those at the earlier time. Superposition of the slightly shifted scattered wavelets will modify the total electric field at the detector to a new value $E(t + \tau)$. Therefore, as time progresses, the electric field at the detector will fluctuate as the Brownian random walks that characterize the diffusion of the particles continue.

The main problem in data recovery in the DLS experiment is the extraction of quantitative information from a fluctuating signal. Since detectors are sensitive to light intensity (which is related to the square of the total electric field), small rapidly diffusing particles will yield rapidly fluctuating intensities, whereas larger particles and aggregates generate relatively slow fluctuations. In modern DLS spectrometers the rate of the fluctuations is measured by autocorrelation analysis of a real-time

Figure 3 A normalized intensity autocorrelation function.

sequence of intensity data that has been digitized into time intervals (sometimes called sampling times) each of which are much shorter than a fluctuation time. The result is an intensity autocorrelation function, $g^{(2)}(\tau)$, where τ is an instrumentally delay time having a value $\tau = kt$, where k is the channel number of the autocorrelation function and t is equivalently the length of the sampling time or the delay time between one channel of $g^{(2)}(\tau)$ and the next. Ideally, the function (see **Figure 3**) has the $\tau = 0$ limit equal to the normalized mean square intensity $\langle I(t)^2 \rangle / \langle I(t) \rangle^2 = 2$ and decays to an asymptotic limit (as τ approaches infinity) equal to the normalized mean intensity squared, $\langle I(t) \rangle^2 / \langle I(t) \rangle^2 = 1$. Practically, however, finite pinhole sizes and the detection optics reduce the $\tau = 0$ intercept from its ideal value.

The rate of decay of $g^{(2)}(\tau)$ is indicative of the typical fluctuation time of the scattering signal and of the rate of diffusion of the scatterers. Quantitatively, $g^{(2)}(\tau)$ can be related to the electric field autocorrelation function through the relation

$$g^{(2)}(\tau) = 1 + |g^{(1)}(\tau)|^2 \quad [2]$$

and when the scatterers are spherical and monodisperse, $g^{(1)}(\tau)$ is related to the translational diffusion coefficient, D , by

$$g^{(1)}(\tau) = e^{-DQ^2\tau} \quad [3]$$

Thus, for such a system, diffusion coefficients can rapidly be obtained by simple least-squares fits of eqn [3] to electric field autocorrelation functions recovered from the experimental intensity autocorrelation functions, or by linear fits to the natural logarithm of $g^{(1)}(\tau)$.

The more common situation is one where the solution contains a size distribution of scatterers. In this situation

$$g^{(1)}(\tau) = \int_0^\infty G(\Gamma) e^{-\Gamma\tau} d\Gamma \quad [4]$$

where $\Gamma = DQ^2$ and $G(\Gamma)$ is the distribution of decay rates that would be obtained from spherical particles whose radius distribution is given by $G(r)$. Since $G(\Gamma)d\Gamma = G(r)dr$ and the Stokes-Einstein relation is

$$D = \frac{k_B T}{6\pi\eta r} \quad [5]$$

where k_B = Boltzmann's constant; T = temperature K and η = coefficient of viscosity then eqn [4] becomes

$$g^{(1)}(\tau) = \int_0^\infty G(r) e^{-\frac{k_B T}{6\pi\eta r} Q^2 \tau} dr \quad [6]$$

In principle, a complete Laplace inversion of eqn [6] would yield the $G(r)$, the radius distribution of the scattering particles. However, this inversion is termed 'ill conditioned' because of mathematical instability and because unattainably high precision in the experimental data is required. Several alternative methods of various complexities have been developed and brief treatments of two of these are given here. The first and most common method of proceeding is called moment analysis or the method of cumulants. Any monomodal distribution can be described in terms of its moments. The object is to obtain these moments of $G(\Gamma)$ without actually performing the inversion. Specifically one attempts to obtain the first and second moments from which one can obtain the mean value and the variance of $G(\Gamma)$ respectively. In this approach the exponential $e^{-\Gamma\tau}$ in eqn [4] is expanded about the mean value $e^{-\bar{\Gamma}\tau}$. The result, after taking the natural logarithm of both sides, becomes a polynomial of the form

$$\ln[g^{(1)}(\tau)] = -\bar{\Gamma}\tau + \frac{\mu_2}{2!}\tau^2 - \frac{\mu_3}{3!}\tau^3 + \dots \quad [7]$$

Most spectrometers contain fitting routines which output the correlation time $\tau_c = \Gamma^{-1}$, the z -average diffusion coefficient and radius, calculated using eqn [5] and μ_2 . Since

$$\mu_2 = \bar{\Gamma}^2 \quad [8]$$

the variance of the distribution can be determined from

$$\text{var} = \bar{\Gamma}^2 - \bar{\Gamma}^2 \quad [9]$$

Most modern spectrometers provide a visual display of the log-normal distribution that has the same mean radius and variance as obtained from the moments analysis of the data. This can be somewhat misleading if the true size distribution of the sample is not close to being log-normal and can be a serious misinterpretation if the sample is multimodal. Some spectrometers do, however, provide enhancements of the above procedure if a sample is suspected to be multimodal. Further, since no consideration has been given to the fact that large particles

scatter more light than small ones, then all the results of moments analysis are intensity weighted or z -averages quantities. The broader the size distribution, the more these quantities can differ from their corresponding number-average quantities.

A variety of mathematically more sophisticated procedures have been developed to approximate the inversion of eqn [6], but without presupposing the form of the size distribution. Most of these approaches are variants of a discrete method in which $g^{(1)}(\tau)$ is fitted to a sum of m exponential functions, each premultiplied by a weighting factor ω_m . The intent is to minimize the sum of squares

$$\left[\left(g^{(1)}(\tau) - \sum \omega_m \exp(-\Gamma_m \tau) \right) \right]^2 \quad [10]$$

with respect to the variables ω_m and Γ_m . As mentioned earlier, this is notoriously unstable, and if no constraints were applied it is essentially impossible to obtain a unique set of best fit parameters. One of the more common restraints is to specify, in advance of the fit, the range and values of a 'trial' set of Γ_m that are expected to span the range of Γ s corresponding to the distribution of particle sizes present. The smallest and largest values of the trial Γ_m (i.e. $m=1$, and $m=m$) can easily be estimated from the final and the initial slopes of $g^{(1)}(\tau)$. In the technique called exponential sampling, the remaining Γ_m s are exponentially spaced between these limiting values. Once all the Γ_m have been preset, only the ω_m s corresponding to the amplitudes, or relative weights of each of the exponentials, remain to be determined by the fit. Even with this simplification there is rarely a single solution with a unique set of ω_m , especially if m is 50 or more. However, by constraining all ω_m to be positive [by using non-negative-least squares (NNLS) methods] a unique set of ω_m can usually be found. Since each Γ_m has a corresponding r_m , plots of ω_m versus r_m represent the radius distribution of the sample. If the data are of sufficient quality (often runs of several hours are necessary) then reliable and reproducible plots of the radius distribution, $G(r)$, can be obtained.

The amplitudes ω_m represent the amount of light scattered by each particle size r_m and represent an intensity weighted distribution of radii. To obtain number distributions one must include the relative scattering ability of each size in the distribution. This can be accomplished by including Rayleigh-Gans-Debye or Mie scattering factors in the analysis. The intensity weighted distribution and the number distribution for a set of phospholipid vesicles is shown in Figure 4.

Although a number of 'user friendly' DLS spectrometers and advanced analytical software packages are available from a number of manufacturers, and size distributions are rapidly and neatly displayed on the computer monitor, it is still important that the user perform a number of checks to ensure that these results are reliable.

Figure 4 Intensity and number distributions obtained from the same DLS data from dioleoylphosphatidylglycerol vesicles prepared by extrusion through filters of 50 nm radius pore size.

If one is safely operating in the single scattering regime (no multiple scattering effects), then the particle size distribution should remain the same if the sample concentration is doubled or halved. The presence of multiple scattering leads to multiple phase shifts in the scattered light which, in turn, lead to 'fictitious' particles with sizes smaller than the true size. On the other hand, if sample concentrations are too small, number fluctuations can lead to particles whose apparent size is erroneously large. The presence of dust particles in the sample must be scrupulously avoided for the same reason. Secondly, it is essential that experimental runs be sufficiently long that the measured autocorrelation function is a true statistical representation of the sample. Recovery of size distributions requires extremely accurate data and it is not uncommon that runs of several hours are necessary to achieve the required level of data quality. Better quality data and more data always lead to more confidence in the result. For this reason, newer multi-angle DLS experiments have been shown to improve the resolution of measured size distribution over single angle determinations.

Samples must be diluted to the point where they are optically almost clear for proper DLS investigations. As a result standard DLS methods cannot be applied to more concentrated suspensions such as milk or paint unless they are diluted extensively. However, DWS can provide estimates of mean particle sizes in concentrated opaque suspensions. The apparatus used in DWS is the same as for DLS except that the incident light and the scattered light are usually conducted through single fibre optics. DWS depends on multiple scattering being so severe that the incident photons experience a random walk (diffusing wave) in the sample before being finally scattered into the returning fibre optic for detection. For back-scatter detection, the simplest form of the DWS electric field autocorrelation function is

$$g^{(1)}(\tau) = \exp \left[-\gamma (6\tau/\tau_0)^{1/2} \right] \quad [11]$$

where $\tau_0 = (Dk_0)^{-1}$. The constant γ must be determined independently by calibration with known size scatterers or by transmission measurements. Once this is done, however, good estimates of D (and therefore r for spherical systems) have been obtained in a variety of dense scattering media.

Static Light Scattering, Small Angle X-Ray and Neutron Scattering

Even though lasers are still commonly used as the source of incident radiation, static scattering does not require coherence. Therefore, other forms of radiation such as X-ray and neutrons, even when pulsed, are suitable sources. The scattering vector dependence of the intensity, $I(Q)$, of the radiation scattered by particles has the form

$$I(Q) = KNm^2 P(Q)S(Q)I_0 \quad [12]$$

where I_0 is the incident radiation intensity, N is the number of particles in the scattering volume, m is the particle mass and K is an instrumental constant. The functions $S(Q)$ and $P(Q)$ are the interparticle scattering factor and the intraparticle scattering factor respectively. The interparticle scattering factor arises from interference between wavelets scattered from different particles. In a suspension this term contains information on the radial distribution function of the scatterers and on their interaction potential. In a more ordered system, where regular spacings are found, this term results in Bragg diffraction peaks when conditions for constructive interference are satisfied. In the case of light scattering, the avoidance of multiple scattering suspensions usually ensures that particle concentrations are sufficiently dilute that interactions are negligible and $S(Q) = 1$. However, since neutrons and X-rays are more penetrating and are scattered more weakly by particles, they are more commonly used at concentrations where interactions are important and where $S(Q) \neq 1$. However, measurements of $S(Q)$ will not be considered here.

The intraparticle scattering factor, $P(Q)$, is related to the structural properties of the scatterer and is the term that contains particle size information. For extremely small noninteracting particles where $r \ll \lambda$, $P(Q)$ approaches unity, and the scattering is said to be isotropic. In this situation eqn [12] greatly simplifies and $I(Q) \propto m^2$. For uniform spherical or globular particles this means that $I(Q) \propto r^6$. If concentrations can be accurately determined by alternative means, then the radius of an unknown particle can be obtained by simple ratios, provided the unknown and the known particles have identical refractive indices.

In the regime where $Q^2 r^2 \ll 1$, the scattering is weakly dependent on Q , and $P(Q)$ can be described by

the Guinier approximation.

$$P(Q) = \exp\left(\frac{Q^2 R_g^2}{3}\right) \quad [13]$$

For small angle scattering (e.g. small angle neutron and X-ray scattering) eqn [13] is further approximated by

$$P(Q) = 1 - \frac{Q^2 R_g^2}{3} \quad [14]$$

For larger particles, explicit Rayleigh–Gans–Debye (RGD) expressions, for $P(Q)$, are known for several different particle shapes and are available in the literature. These RGD functions are valid if the condition

$$Q^2 r^2 \left(\frac{n^2}{n_0^2} - 1\right) < 1 \quad [15]$$

is satisfied (n is the refractive index of the particle and n_0 is the refractive index of the medium). For the case of scattering of vertically polarized incident light from uniform spherical particles, $P(Q)$ has the form

$$P(Q) = \left(\frac{n}{n_0} - 1\right)^2 \left[\frac{3}{u^3}(\sin u - u \cos u)\right]^2 \quad [16]$$

where $u = Qr$.

When particle sizes are too large to satisfy the RGD criterion then Mie theory must be used to evaluate scattering factors. The need for a more sophisticated theory arises because wavefronts of the incident light do not remain planar as they traverse large particles, thereby altering intraparticle interference and the angular dependence of the scattered light. For vertically polarized incident light, the angle dependence of the scattered light is contained in the S_{11} component of the Mueller matrix:

$$S_{11}(\cos \theta, n, n_0, r) = \sum_{j=1}^{\infty} \frac{2j+1}{j(j+1)} (a_j \pi_j + b_j \tau_j) \quad [17]$$

where

$$\pi_j = \frac{P_j^1 \cos(\theta)}{\sin(\theta)} \quad \text{and} \quad \tau_j = \frac{d}{d\theta} P_j^1 \cos(\theta) \quad [18]$$

and $P_j^1 \cos(\theta)$ is the associated Legendre polynomial. The scattering coefficients, a_j and b_j , are known only for spherical systems such as uniform spheres, hollow shells and coated spheres.

Fraunhofer scattering has become a popular optical sizing tool for particles substantially larger than a micrometre in diameter. In this case each particle behaves similarly to a pinhole aperture, and the low angle scattered light is a superposition of Fraunhofer diffraction patterns. This technique is widely used for the analysis of commercial food-based emulsions and sauces.

Figure 5 Experimental SAXS data from a composite latex with a polystyrene core and a poly(methyl methacrylate) shell. The number average diameter is 92.8 nm. The inset displays the electron density cross section of the particle derived from contrast variation studies. Reproduced with permission of Hühlig & Wepf Verlag from Ballauff MB, Bolze J, Dingenouts N, Hickl P. and Pötschke D (1996) Small-angle X-ray scattering on latexes. *Macromolecular Chemistry and Physics* 197: 3043–3066.

Since X-rays and neutrons have relatively low scattering cross sections for most particulate suspensions, RGD scattering factors apply extremely well in the analysis of SAXS and SANS data, even when the scattering particles are above the size limitations imposed by eqn [15]. Expressions equivalent to eqns [12] and [16] have been written down for X-ray and neutron scattering. In addition to particle size analysis, these techniques, SANS especially, offer the ability to use contrast variation methods to enhance the scattering from the structure or substructure of interest. For SANS studies of water-soluble particles, this can be accomplished by varying the H₂O:D₂O ratio in the solvent mixture or by exchanging deuterium for hydrogen in the scatterer. For SAXS the contrast variation can be accomplished if heavy atoms can be strategically attached to the scatterer (**Figure 5**).

Effects due to polydispersity are also important in the analysis of static light scattering data. For a polydisperse sample, eqn [12] becomes

$$I(Q) = I_0 K N \int_0^{\infty} M^2(r) P(Q, n, n_0, r) G(r) dr \quad [19]$$

Recovery of the distribution of radii [$G(r)$] present in the sample requires the inversion of eqn [21] and as for dynamic light scattering (see eqn [6]) this transform is ill conditioned. However, discrete methods analogous to those used for DLS have been applied successfully, thereby allowing size distributions to be obtained from SLS data. Depending on the particle size range, $P(Q, n, n_0, r)$ can be Guinier, RGD, or Mie, with the latter being

Figure 6 Number distribution of particle sizes from a sample of microfluidized milk obtained by the inversion of $I(Q)$ data from SLS.

the most universal. **Figure 6** demonstrates a size distribution of microfluidized milk obtained from the inversion $I(Q)$ from SLS data according to eqn [19] and assuming the sample behaves as uniform spherical particles. This is corroborated by electron microscopic studies in this case. However, knowledge of the shape and structure (e.g. sphere, coated sphere, rod, Gaussian coil, etc.) is not always available. If the wrong morphology is assumed then the inversion results can be meaningless. In addition, for SLS, $I(Q)$ data from particle sizes below ~ 100 nm in diameter is so close to being isotropic that inversion and recovery of size distributions become impossible. The opposite limitation arises in SANS and SAXS. Because of the significantly shorter wavelengths of neutrons and X-rays, the upper limit on diameter for particle sizing for these techniques is typically 100 nm (see **Figure 2**). Finally, as for DLS the need for extremely high quality data is just as vital for the successful recovery of particle size distributions, and all inversion routines work best when the distributions are unimodal and relatively narrow. To improve the recovery of broad size distributions and multimodal distributions, SLS measurements have sometimes been combined with sample fractionation techniques. The most successful of these devices, multi-angle light scattering-field flow fractionation (MALS-FFF) spectrometers, shows great promise for sizing complex particulate mixtures.

Symbols

$ A\rangle$	initial state of atom
$a_{k\lambda}$	photon annihilation operator for mode $k\lambda$
$a_{k\lambda}^\dagger$	photon creation operator for mode $k\lambda$
b	bound scattering length of atomic nucleus
B	magnetic field vector
$ B\rangle$	final state of atom
c	speed of light in vacuum
D	diffusion coefficient
dP	time-averaged power scattered into solid angle $d\Omega$
dR	rate of scattering into solid angle $d\Omega$
$(d\sigma/d\Omega)_l$	angular differential cross-section for scattering by the l th atom
$(d\sigma/d\Omega)_{if}$	angular differential cross-section for target in specific initial state $ E_i\rangle$ and final state $ E_f\rangle$
$d\sigma/d\Omega$	angular differential cross-section
$d^2\sigma/d\Omega dE'$	double differential cross-section
$(d\sigma/d\Omega)_0$	angular differential cross-section from single scattering unit
$d^2\sigma/d\Omega d\omega$	$d^2\sigma/d\Omega dE'$ multiplied by $\hbar$
$(d\sigma/d\Omega)_l^{\text{Rayleigh}}$	angular differential cross-section for Rayleigh scattering by the l th atom
$d\Omega$	differential solid angle
e	electronic charge
e_r	unit vector in direction of r
E	energy of incident radiation quantum
E	electric field vector
E_0	electric field vector for incident wave
E_A	initial energy of atom
E'	energy of scattered radiation quantum
E_f	energy of target medium after scattering
$ E_f\rangle$	quantum state of target medium after scattering
E_i	energy of target medium before scattering
E_i	energy of intermediate state of radiation/target system

$ E_i\rangle$	quantum state of target medium before scattering
E_J	energy of intermediate atomic state
E_m	energy of radiation/target system before scattering
E_n	energy of radiation/target system after scattering
E_R	recoil energy of target particle
E_s	electric field vector for scattered wave
$F(Q, t)$	intermediate scattering function
$F_s(Q, t)$	self-intermediate scattering function
$F_s^c(Q, t)$	classical self-intermediate scattering function
$g(E_n)$	density of final states
$\tilde{G}$	Green's tensor
η	$\hbar/2\pi$, where $\hbar$ is Planck's constant
H_0	Hamiltonian of incident radiation + scattering medium, with no interaction present
H_S	Hamiltonian of scattering medium
H_R	Hamiltonian of incident radiation
i	square-root of -1
$\tilde{I}$	unit dyad
$ I\rangle$	an intermediate state of radiation/target system
$ J\rangle$	an intermediate atomic state
k	wavenumber of incident radiation
k_B	Boltzmann's constant
k_v	wavenumber of light in vacuum
k	wavevector of incident radiation
k'	wavenumber of scattered radiation
k'	wavevector of scattered radiation
$ k\lambda\rangle$	quantum state of incident radiation quantum
$ k'\lambda'\rangle$	quantum state of scattered radiation quantum
L^3	volume of region in which radiation is confined
m	mass of electron
$ m\rangle$	quantum state of radiation/target system before scattering
M	mass of scattering particle
n	index of refraction of medium
$ n\rangle$	quantum state of radiation/target system after scattering
$n_{k\lambda}$	number of photons in mode $k\lambda$

$\bar{n}$	average index of refraction of medium
N	number of atoms
P_i	Maxwell–Boltzmann probability distribution for target in different initial energy states $ E_i\rangle$
Q	wave vector transfer
r	position vector of field-point where radiation is detected
r'	position vector of source-point inside scattering medium
r_0	classical electron radius
R_l	location of l th atom
$S(Q)$	static structure factor
$S_S(Q, \omega)$	self-dynamic structure factor
$S_S^{\text{cl}}(Q, \omega)$	classical self-dynamic structure factor
$S(Q, \omega)$	dynamic structure factor
t	time
T	absolute temperature
T	transition matrix
V	interaction potential between radiation and scatterer
V_0	speed, $k_B T/M$
W	transition probability per unit time
$W(t)$	width function or mean-square displacement function
$\tilde{\alpha}_l$	atomic polarizability tensor for l th atom
α_l	scalar polarizability of l th atom
$\Delta\rho(Q, t)$	spatial Fourier transform of local number-density fluctuations in scattering medium
Δn	local fluctuation in refractive index
$\Delta\epsilon$	local fluctuation in permittivity
$\Delta\rho(r', t)$	local fluctuation in number density in scattering medium
ϵ	electric permittivity of scattering medium
ϵ_0	electric permittivity of vacuum
$\epsilon_{k\lambda}$	unit polarization vector for mode $k\lambda$
$\bar{\epsilon}$	average permittivity of medium
θ	polar angle
λ	polarization of incident radiation
λ'	polarization of scattered radiation
μ_l	electric dipole moment of l th atom
μ_k^l	product of $\epsilon_{k\lambda}$ and μ_l
μ_k^l	product of $\epsilon_{k\lambda'}$ and μ_l
$\bar{\rho}$	average number density in scattering medium
$\rho(r', t)$	local number density in scattering medium
$\rho(Q, t)$	spatial Fourier transform of local number density in scattering medium
σ	scattering cross-section.
Φ_{in}	incident flux
ϕ	azimuthal angle

ω	angular-frequency shift of radiation due to scattering
ω_0	angular frequency of light

The term ‘scattering’ refers to an interaction between an incident radiation and a target material resulting in a redirection, and possibly a change in energy, of the incident radiation. In effect, there is an exchange of momentum and energy between the radiation and target. From a fundamental standpoint, the scattering of photons, neutrons, and charged particles from atomic and molecular systems needs to be treated quantum-mechanically. On the other hand, for electromagnetic radiation having wavelengths near or larger than those in the visible region of the spectrum, a classical wave approach is justified as well. In either case, the aim of any useful scattering theory is to provide the calculational framework for predicting the quantity most readily measured in the laboratory, namely the flux or intensity of radiation scattered into a detector. Ultimately, the connection between a scattering measurement and theory is made through a quantity known as the double-differential scattering cross-section.

Scattering Cross-Sections

A scattering cross-section, σ , is a quantity proportional to the rate at which a particular radiation–target interaction occurs. More specifically, if the incoming radiation is considered as being composed of quanta or ‘particles’ (for example, photons or neutrons), a cross-section is a scattering rate (number of scattering events per unit time) per unit incident radiation flux, where the latter is the number of incident particles striking the target surface per unit time per unit area. In cases where the radiation is being treated as a continuous classical wave, as in the case of long-wavelength electromagnetic radiation, scattering cross-sections are determined by dividing the power of the scattered wave by the intensity of the incident wave. Dimensionally, a cross-section represents an area, with the basic unit being the barn, which represents an area of 10^{-28} m^2 . A scattering cross-section should not be interpreted as a true geometric cross-sectional area, but as an effective area that is proportional to the probability of interaction between the radiation and target.

In a laboratory setting, one measures differential scattering cross-sections. These are determined by placing a detector at a particular angular position at a substantial distance away from the scattering target. **Figure 1** shows a standard scattering geometry. The incident beam travels in the positive z -direction and one considers the radiation scattered into a differential solid angle $d\Omega$ at polar angle θ and azimuthal angle ϕ . One can then measure an angular

Figure 1 Standard scattering geometry for measuring differential scattering cross-section.

differential scattering cross-section (in barn steradian⁻¹) given by

$$\frac{d\sigma}{d\Omega} = \frac{dR/d\Omega}{\Phi_{in}} \quad [1]$$

where dR is the rate of scattering into solid angle $d\Omega$, and Φ_{in} is the incident flux. The most fundamental type of cross-section is the double-differential scattering cross-section, $d^2\sigma/d\Omega dE'$. The quantity $[d^2\sigma/(d\Omega dE')] d\Omega dE'$ is the number of particles, each with incident energy E , scattered (per unit time) into solid angle $d\Omega$ with energy between E' and $E' + dE'$, divided by the flux of the incident beam. Once the double-differential cross-section is derived or measured, $d\sigma/d\Omega$ and σ can be calculated by integrating over the energy of the scattered radiation and solid angle.

Development of the Double-Differential Cross-Section

From a quantum mechanical standpoint, the calculation of the double-differential cross-section is based on time-dependent perturbation theory, which provides the general framework for calculating transition rates between quantum states.

A scattering event is a type of transition between two states of the combined system of incident particle + scattering medium. Take the system's unperturbed Hamiltonian H_0 to be

$$H_0 = H_S + H_R \quad [2]$$

where H_S and H_R are the Hamiltonians of the scatterer and radiation, respectively, assuming no interaction between the two. The combined system is in an eigenstate of H_0 both before and after the scattering interaction takes place. Employing Dirac notation, let the kets $|E_i\rangle$ and $|E_f\rangle$ denote the initial and final energy eigenstates of the scatterer, i.e.

$$H_S|E_i\rangle = E_i|E_i\rangle \quad \text{and} \quad H_S|E_f\rangle = E_f|E_f\rangle \quad [3]$$

Figure 2 Setup for deriving a double-differential scattering cross-section.

If k is the wavenumber ($2\pi/\text{wavelength}$) of the incident beam, a quantum of the incident radiation is represented by an eigenstate $|k\lambda\rangle$ of definite momentum $\hbar k$ and polarization (or spin) λ (see **Figure 2**). The scattered quantum falls into state $|k'\lambda'\rangle$. These are also energy eigenstates, i.e.

$$H_R|k\lambda\rangle = E|k\lambda\rangle \quad \text{and} \quad H_R|k'\lambda'\rangle = E'|k'\lambda'\rangle \quad [4]$$

Again, E and E' are the energies of the incident and scattered particles. For the composite system, the initial state $|m\rangle$ and final state $|n\rangle$ are given by the products

$$|m\rangle = |k\lambda\rangle|E_i\rangle \quad \text{and} \quad |n\rangle = |k'\lambda'\rangle|E_f\rangle \quad [5]$$

which are eigenstates of H_0 , so

$$H_0|m\rangle = E_m|m\rangle \quad \text{and} \quad H_0|n\rangle = E_n|n\rangle \quad [6]$$

where the initial and final energies of the system are $E_m = E_i + E$ and $E_n = E_f + E'$, respectively.

Time-dependent perturbation theory gives rise to the following general result for the transition probability per unit time between initial state $|m\rangle$ and final state $|n\rangle$:

$$W(m \rightarrow n) = \frac{2\pi}{\hbar} |\langle n|\mathbf{T}|m\rangle|^2 g(E_n) \quad [7]$$

Here, $g(E_n)$ denotes the density of final states for the system, where $g(E_n)dE_n$ is the number of final states between E_n and $E_n + dE_n$. $\langle n|\mathbf{T}|m\rangle$ is called the transition matrix or $\mathbf{T}$ -matrix, and it is based on V , the interaction potential between the incident radiation and the scatterer, according to the expansion

$$\langle n|\mathbf{T}|m\rangle = \langle n|V|m\rangle + \sum_I \frac{\langle n|V|I\rangle\langle I|V|m\rangle}{E_m - E_I} + \dots \quad [8]$$

Basically, the interaction potential induces scattering events and, hence, transitions between the initial and final states of the combined system. When the first term, i.e. matrix element $\langle n|V|m\rangle$, is the only one responsible for transitions, one says that the transition is first-order in

the perturbation, and eqn [7] is referred to as Fermi's golden rule. Higher-order transitions require passing through some intermediate states, denoted here by I , between the specified initial and final states.

Once the transition rate is developed for a specific type of interaction, eqn [1] can be used to obtain the angular differential cross-section, $d\sigma/d\Omega$. For a target in a known initial state $|E_i\rangle$ and known final state $|E_f\rangle$, one writes

$$\left(\frac{d\sigma}{d\Omega}\right)_{if} = \frac{dR_{if}}{\Phi_{in}} = \frac{W(E_i, k\lambda \rightarrow E_f, k'\lambda')}{\Phi_{in}} \quad [9]$$

In this equation, Φ_{in} now represents the flux of a single incident particle. It is usually the case, however, that the scatterer is not initially in one of its pure eigenstates. Instead, the target is normally in thermal equilibrium at some known temperature T . In this case, the scatterer is in a 'mixed quantum state' and it is necessary to perform a summation over possible initial states, $|E_i\rangle$, weighted according to the Maxwell-Boltzmann probability distribution, $P_i = \exp(-E_i/k_B T) / \sum_j \exp(-E_j/k_B T)$, where k_B is Boltzmann's constant. The angular differential cross-section then becomes

$$\frac{d\sigma}{d\Omega} = \frac{\sum_i P_i W(E_i, k\lambda \rightarrow E_f, k'\lambda')}{\Phi_{in} d\Omega} \quad [10]$$

The procedure for obtaining the double-differential scattering cross-section is to now sum over possible final states $|E_f\rangle$ of the scatterer, subject to the condition that the energy of the combined system of radiation + target is conserved. The latter is accomplished by attaching the Dirac delta function, $\delta(E_m - E_n)$, to each term in the sum. Finally, we can introduce

$$\hbar\omega = E - E' \quad [11]$$

which is an important parameter that represents the energy transferred to the material medium by a quantum of the radiation. Putting these ideas together gives the following expression for the double-differential cross-section:

$$\begin{aligned} & \frac{d^2\sigma}{d\Omega d\omega} \\ &= \hbar \frac{d^2\sigma}{d\Omega dE'} \\ &= \frac{\hbar \sum_{i,f} P_i W(E_i, k\lambda \rightarrow E_f, k'\lambda') \delta[\hbar\omega - (E_f - E_i)]}{\Phi_{in} d\Omega} \quad [12] \end{aligned}$$

Light Scattering – an Example

The purpose of this section is to illustrate, for a specific case, the derivation of the angular and double-differential scattering cross-section just outlined. The vehicle chosen is the scattering of visible light from a collection of N optically isotropic atoms in thermal equilibrium. As will be seen, the calculation culminates in a central quantity

known as the dynamic structure factor, which appears not only in light scattering, but in the scattering of X-rays and thermal neutrons as well.

For optical frequencies, where the wavelength of light is large compared with the size of an atom, the interaction occurs through the coupling of the radiation to the electric dipole moment μ of each atom in the target material. The Hamiltonian of the atomic system in the presence of the electromagnetic (EM) field of the light beam is

$$H = H_S + H_R - \sum_l \mu_l \cdot E(R_l) \quad [13]$$

where H_S is the Hamiltonian of the atomic system in the absence of the EM field, H_R is the Hamiltonian of the pure light field, and the last term represents the sum of the interactions between the dipole moment of the l th atom in the system and the light's electric field vector, E , at the location R_l of that atom.

The present derivation of the scattering cross-section is based on a non-relativistic quantum electrodynamic approach. In this picture, the modes of the radiation field are quantized and the electric field is treated as a quantum-mechanical operator that annihilates or creates photons populating the various modes. The field operator is given by

$$\begin{aligned} E(R_l) = \sum_{k\lambda} i \sqrt{\frac{\hbar c k}{2\epsilon_0 L^3}} \epsilon_{k\lambda} [a_{k\lambda} \exp(ik \cdot R_l) \\ - a_{k\lambda}^\dagger \exp(-ik \cdot R_l)] \quad [14] \end{aligned}$$

At the initial stage of the calculation it is necessary to imagine that the radiation field is confined to a region of space having volume L^3 ; however, this volume drops out of the calculation shortly. The term $\epsilon_{k\lambda}$ is the unit polarization vector of photon state $|k\lambda\rangle$. $a_{k\lambda}$ and $a_{k\lambda}^\dagger$ are sometimes called the photon 'annihilation' and 'creation' operators. $a_{k\lambda}$ has the effect of lowering the number of photons $n_{k\lambda}$ in state $k\lambda$ to $n_{k\lambda} - 1$, whereas $a_{k\lambda}^\dagger$ raises the number of photons from $n_{k\lambda}$ to $n_{k\lambda} + 1$.

The transition rate for the l th atom is now given by eqn [7], where the interaction potential associated with the transition matrix is $\mu_l \cdot E(R_l)$. If the atom is initially in state $|A\rangle$, then the combined initial state for the field + atom is $|m\rangle = |1_{k\lambda}, 0_{k'\lambda'}\rangle |A\rangle$, indicating that there is one photon in incident mode $k\lambda$ and no photons in the scattered mode $k'\lambda'$. Likewise, the final state is $|n\rangle = |0_{k\lambda}, 1_{k'\lambda'}\rangle |B\rangle$. Because of the action of the operators $a_{k\lambda}$ and $a_{k\lambda}^\dagger$, along with the orthogonality property of the photon states, the terms in the perturbation expansion of the transition matrix can only be non-zero if the initial and final states differ by unity in one, and only one, mode of the field. A careful inspection shows that all terms in the perturbation expansion vanish except for the second-order contributions. These are terms that involve intermediate

Figure 3 Feynman diagrams for the two types of virtual transitions associated with the scattering of a photon by an atom.

states, $|I\rangle$, of the combined system, which are sometimes referred to as virtual states. For single photon scattering, two types of virtual transitions can occur, as illustrated by the Feynman diagrams in **Figure 3**. In the first type of transition, we have the intermediate state $|I\rangle = |0_{k\lambda}, 0_{k'\lambda'}\rangle |J\rangle$, where one pictures that an intermediate atomic state $|J\rangle$ is created when the incident $k\lambda$ -photon is absorbed; the scattered $k'\lambda'$ -photon is then born, leaving the atom in final state $|B\rangle$. In the second type of transition, the intermediate state is represented by $|I\rangle = |1_{k\lambda}, 1_{k'\lambda'}\rangle |J\rangle$ where one imagines that the scattered $k'\lambda'$ -photon appears before the incident $k\lambda$ -photon is absorbed.

Because their existence is not real, transitions to and from the virtual states do not need to conserve energy. However, the energies of the initial state and the final state must match exactly, i.e. $E_A + \hbar ck = E_B + \hbar ck'$. Taking this into account, the transition matrix for atom l works out to be the sum of two terms

$$\begin{aligned} \langle n|\mathbf{T}|m\rangle_l = & -\frac{\hbar c}{2\epsilon_0 L^3} \sqrt{k k'} \exp[i(\mathbf{k} - \mathbf{k}') \cdot \mathbf{R}_l] \\ & \times \sum_J \left(\frac{\langle B|\mu_{k'}^l|J\rangle \langle J|\mu_k^l|A\rangle}{E_A - E_J - \hbar ck} \right) \\ & + \frac{\langle B|\mu_k^l|J\rangle \langle J|\mu_{k'}^l|A\rangle}{E_A - E_J - \hbar ck'} \end{aligned} \quad [15]$$

where $\mu_k^l = \epsilon_{k\lambda} \cdot \boldsymbol{\mu}_l$ and $\mu_{k'}^l = \epsilon_{k'\lambda'} \cdot \boldsymbol{\mu}_l$. Details leading to this result can be found in the Further Reading section.

Carrying out the calculation of the scattering cross-section also requires the incident flux associated with a single photon, which is

$$\Phi_{\text{in}} = c/L^3 \quad [16]$$

and the density of states factor for a photon (of a specified polarization) scattered into solid angle $d\Omega$ about wave vector $\mathbf{k}'$. If recoil of the atom is neglected, the expression is given by

$$g(E_n) = \left(\frac{L}{2\pi} \right)^3 \frac{k'^2}{\hbar c} d\Omega \quad [17]$$

One now has the following expression for the angular differential cross-section for the scattering of light by the l th atom:

$$\begin{aligned} \left(\frac{d\sigma}{d\Omega} \right) = & \frac{k k'^3}{(4\pi\epsilon_0)^2} \left| \sum_J \left(\frac{\langle B|\mu_{k'}^l|J\rangle \langle J|\mu_k^l|A\rangle}{E_A - E_J + \hbar ck} \right. \right. \\ & \left. \left. + \frac{\langle B|\mu_k^l|J\rangle \langle J|\mu_{k'}^l|A\rangle}{E_A - E_J + \hbar ck'} \right) \right|^2 \end{aligned} \quad [18]$$

This result is valid for either inelastic Raman scattering or elastic Rayleigh scattering. For the case of Raman scattering, $|A\rangle$ and $|B\rangle$ are different discrete electronic states of the atom, hence the frequency of the scattered photon is either less than or greater than the frequency of the incident radiation. A down-shifted frequency gives rise to the so-called Stokes spectral line, whereas an up-shifted frequency corresponds to the anti-Stokes line. In the case of Rayleigh scattering, the atom returns to its original state, so that $|B\rangle = |A\rangle$ and $\mathbf{k}' = \mathbf{k}$. The cross-section then becomes

$$\left(\frac{d\sigma}{d\Omega} \right)_l^{\text{Rayleigh}} = \frac{k^4}{(4\pi\epsilon_0)^2} |\epsilon_{k\lambda} \cdot \tilde{\alpha}_l(\mathbf{k}) \cdot \epsilon_{k'\lambda'}|^2 \quad [19]$$

where we define the *atomic polarizability tensor* for atom l to be

$$\begin{aligned} \tilde{\alpha}_l(\mathbf{k}) = & \sum_J \left(\frac{\langle A|\mu_l|J\rangle \langle J|\mu_l|A\rangle}{E_A - E_J + \hbar ck} \right. \\ & \left. + \frac{\langle A|\mu_l|J\rangle \langle J|\mu_l|A\rangle}{E_A - E_J - \hbar ck} \right) \end{aligned} \quad [20]$$

If the atomic charge distribution is spherically symmetric, then the polarizability is a scalar quantity and

$$\left(\frac{d\sigma}{d\Omega} \right)_l^{\text{Rayleigh}} = \frac{k^4}{(4\pi\epsilon_0)^2} |\epsilon_{k\lambda} \cdot \epsilon_{k'\lambda'}|^2 |\alpha_l(\mathbf{k})|^2 \quad [21]$$

The well-known k^4 -dependence of the cross-section is responsible for pronounced Rayleigh scattering of light at the short-wavelength end of the visible spectrum.

Now consider the full system of N atoms in thermal equilibrium. Recall from eqn [15] that the transition matrix for a given atom contains a phase factor $e^{i(\mathbf{k}-\mathbf{k}') \cdot \mathbf{R}'}$ that depends on the position of that atom. At this point, let us introduce the momentum transferred to the material medium as

$$\hbar \mathbf{Q} = \hbar \mathbf{k} - \hbar \mathbf{k}' \quad [22]$$

$\mathbf{Q}$ is usually referred to as the wave vector transfer (see **Figure 2**). The angular cross-section for coherent scattering from all the atoms of the system is obtained by first summing the transition matrix element over l , then squaring the result, and finally averaging over the initial

energy states associated with the thermal motion of the atoms at equilibrium temperature T . In the case of identical atoms, all with the same polarizability α , the cross-section reduces to

$$\left(\frac{d\sigma}{d\Omega}\right) = N \left(\frac{d\sigma}{d\Omega}\right)_0 S(\mathbf{Q}) \quad [23]$$

where $(d\sigma/d\Omega)_0 = [k^4/(4\pi\epsilon_0)^2] |\epsilon_{k\lambda} \cdot \epsilon_{k'\lambda'}|^2 |\alpha|^2$ is the Rayleigh scattering cross-section for a single atom and

$$\begin{aligned} S(\mathbf{Q}) &= \frac{1}{N} \sum_i P_i \left\langle E_i \left| \sum_{l=1}^N \exp(i\mathbf{Q} \cdot \mathbf{R}_l) \right| E_i \right\rangle \\ &= \frac{1}{N} \left\langle \sum_{l,l'} \exp[-i\mathbf{Q} \cdot (\mathbf{R}_l - \mathbf{R}_{l'})] \right\rangle \end{aligned} \quad [24]$$

is called the 'static structure factor'. The large angled bracket represents an ensemble average at temperature T . The function $S(\mathbf{Q})$ reflects the spatial correlations between pairs of particles in the scattering medium.

To write the double-differential cross-section, the expression for $(d\sigma/d\Omega)$ is summed over the final motional states with the inclusion of an energy conservation factor, i.e.

$$\frac{d^2\sigma}{d\Omega d\omega} = N \left(\frac{d\sigma}{d\Omega}\right)_0 S(\mathbf{Q}, \omega) \quad [25]$$

where

$$\begin{aligned} S(\mathbf{Q}, \omega) &= \frac{1}{N} \sum_{i,f} P_i \left\langle E_f \left| \sum_{l=1}^N \exp(i\mathbf{Q} \cdot \mathbf{R}_l) \right| E_i \right\rangle^2 \\ &\times \delta\left(\omega - \frac{E_f - E_i}{\hbar}\right) \end{aligned} \quad [26]$$

is the aforementioned dynamic structure factor. By using an integral representation of the delta function

$$\begin{aligned} \delta\left(\omega - \frac{E_f - E_i}{\hbar}\right) &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} dt \exp(-i\omega t) \\ &\times \exp[i(E_f - E_i)t/\hbar] \end{aligned} \quad [27]$$

the structure factor can (with some work) be transformed into the following more useful form:

$$\begin{aligned} S(\mathbf{Q}, \omega) &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} dt \exp(-i\omega t) \\ &\times \left\langle \frac{1}{N} \sum_{l,l'} \exp[-i\mathbf{Q} \cdot \mathbf{R}_l(0)] \exp[i\mathbf{Q} \cdot \mathbf{R}_{l'}(t)] \right\rangle \end{aligned} \quad [28]$$

$S(\mathbf{Q}, \omega)$ is determined by the spatial and temporal correlations between the various atoms in the scattering medium.

Integrating the dynamic structure factor over ω produces the expression for the static structure factor, $S(\mathbf{Q})$.

Scattering of Classical Electromagnetic Waves

Light scattering can also be treated in the framework of classical EM waves. Since Maxwell's equations accurately describe electromagnetic phenomena almost down to the atomic scale, one might ask whether it is really necessary to go through the detailed quantum treatment previously described. To answer this question, the classical approach is outlined below.

Consider Maxwell's equations for the electric and magnetic field vectors, $\mathbf{E}$ and $\mathbf{B}$, in a nonmagnetic scattering medium void of free charges and currents. Assigning an $\exp(-i\omega_0 t)$ time-dependence to all fields, two of the equations (Faraday's law and Ampere's law) become the pair

$$\nabla \times \mathbf{E} - i c \mathbf{k}_v \mathbf{B} = 0 \quad [29]$$

$$\nabla \times \mathbf{B} + i \frac{n^2 \mathbf{k}_v}{c} \mathbf{E} = 0 \quad [30]$$

$k_v = \omega_0/c$ is the wavenumber of the light in vacuum and $n = (\epsilon/\epsilon_0)^{1/2}$ is the refractive index of the medium (ϵ and ϵ_0 are the permittivity of the medium and vacuum, respectively). Eliminating $\mathbf{B}$ from the equations results in a single equation for the electric field:

$$\nabla \times \nabla \times \mathbf{E} - n^2 \mathbf{k}_v^2 \mathbf{E} = 0 \quad [31]$$

The triple product becomes $\nabla \times \nabla \times \mathbf{E} = \nabla(\nabla \cdot \mathbf{E}) - \nabla^2 \mathbf{E}$. However, Gauss's law for a charge-free region is $\nabla \cdot \mathbf{E} = 0$, so the result is the following equation for the field:

$$\nabla^2 \mathbf{E} + n^2 \mathbf{k}_v^2 \mathbf{E} = 0 \quad [32]$$

For a homogeneous medium with uniform index of refraction $n = \bar{n}$, the solution to eqn [32] is a propagating plane-wave with modified wavenumber $k = \bar{n} k_v$. For scattering to occur, there must be local refractive-index fluctuations present:

$$\begin{aligned} \Delta n^2(\mathbf{r}, t) &= n^2(\mathbf{r}, t) - \bar{n}^2 \\ &= \frac{\epsilon(\mathbf{r}, t) - \bar{\epsilon}}{\epsilon_0} = \frac{\Delta\epsilon(\mathbf{r}, t)}{\epsilon_0} \end{aligned} \quad [33]$$

Equation [32] then becomes

$$\nabla^2 \mathbf{E} + \mathbf{k}^2 \mathbf{E} = -\frac{\Delta\epsilon(\mathbf{r}, t)}{\epsilon_0} \mathbf{k}_v^2 \mathbf{E} \quad [34]$$

where $\Delta\epsilon(\mathbf{r}, t)/\epsilon_0$ represents local fluctuations of the relative permittivity (dielectric constant) in the target. The task of classical light-scattering theory has been reduced to

solving eqn [34]. The only role of quantum theory, therefore, is to calculate the atomic polarizability α – in other words, the microscopic properties of the scattering medium. Once this is achieved, the polarizability can then be related to the dielectric constant through the well-known Clausius–Mossotti relation.

The scattered wave reaching location $\mathbf{r}$ is constructed from the Green's tensor $\tilde{G}(\mathbf{r}-\mathbf{r}')$, which is the solution to eqn [34] with the right-hand side, or source term, replaced by $\tilde{I}\delta(\mathbf{r}-\mathbf{r}')$ where $\tilde{I}$ is the unit dyad. The delta function represents a point scatterer situated at $\mathbf{r}'$. For a field point far from the scatterer, i.e. $r \gg r'$, the form of the Green's tensor is

$$\tilde{G}(\mathbf{r}-\mathbf{r}') = (\tilde{I} - \mathbf{e}_r \mathbf{e}_r) \frac{\exp[ik_r r]}{4\pi r} \exp[-i\mathbf{k}' \cdot \mathbf{r}'] \quad [35]$$

where $\mathbf{e}_r$ is the unit vector in the direction of $\mathbf{r}$, and $\mathbf{k}' = k\mathbf{e}_r$ denotes the scattered wave vector. The scattered wave, $E_s(\mathbf{r}, t)$, corresponds to the inhomogeneous solution to eqn [34]. It is constructed from the Green's tensor to be the following integral over points $\mathbf{r}'$ in the scattering volume:

$$E_s(\mathbf{r}, t) = \int_V d^3 r' \tilde{G}(\mathbf{r}-\mathbf{r}') \cdot \frac{\Delta\epsilon(\mathbf{r}', t)}{\epsilon_0} \mathbf{k}_v^2 E(\mathbf{r}', t) \quad [36]$$

If scattering from the medium is sufficiently weak, one is justified in applying the so-called Rayleigh–Gans–Debye approximation. This simply says that the field inside the scatterer may be approximated to be the same as the field of the incident light. That is, one makes the replacement $E(\mathbf{r}', t) = E_0 \exp[i(\mathbf{k} \cdot \mathbf{r} - \omega_0 t)]$, which leads to

$$E_s(\mathbf{r}, t) = \frac{k_v^2}{4\pi\epsilon_0} \frac{\exp[ik_r r - i\omega_0 t]}{r} (\tilde{I} - \mathbf{e}_r \mathbf{e}_r) \cdot E_0 \int_V d^3 r' \Delta\epsilon(\mathbf{r}', t) \exp(i\mathbf{Q} \cdot \mathbf{r}') \quad [37]$$

In the case of condensed phases, fluctuations in the dielectric constant may contain a slow time-dependence caused by slowly varying density fluctuations on length-scales of the same order of magnitude as the wavelength of light. The dielectric fluctuations may then be replaced by fluctuations in the number density $\Delta\rho(\mathbf{r}', t)$ according to

$$\Delta\epsilon(\mathbf{r}', t) = \left(\frac{\partial\epsilon}{\partial\rho} \right)_T \Delta\rho(\mathbf{r}', t) \quad [38]$$

where $\Delta\rho(\mathbf{r}', t) = \rho(\mathbf{r}', t) - \bar{\rho}$ with $\bar{\rho}$ being the average density of the material. Furthermore, if one denotes the spatial Fourier transform of $\Delta\rho(\mathbf{r}', t)$ by

$$\Delta\rho(\mathbf{Q}, t) = \int_V d^3 r' \Delta\rho(\mathbf{r}', t) \exp(i\mathbf{Q} \cdot \mathbf{r}') \quad [39]$$

then the scattered field becomes

$$E_s(\mathbf{r}, t) = \frac{k_v^2}{4\pi\epsilon_0} \frac{\exp[i(\mathbf{k} \cdot \mathbf{r} - \omega_0 t)]}{r} \times (\tilde{I} - \mathbf{e}_r \mathbf{e}_r) \cdot E_0 \left(\frac{\partial\epsilon}{\partial\rho} \right)_T \Delta\rho(\mathbf{Q}, t) \quad [40]$$

This clearly shows that light scattering arises because of local density fluctuations in the medium.

The angular differential cross-section is calculated by taking $dP/d\Omega$, where dP is the time-averaged power scattered into solid angle $d\Omega$, and dividing by the intensity of the incident light. This is equivalent to writing $d\sigma/d\Omega = r^2 \langle |\mathbf{E}_s|^2 \rangle / |\mathbf{E}_0|^2$, so that

$$\frac{d\sigma}{d\Omega} = \frac{k_v^4}{(4\pi\epsilon_0)^2} \left(\frac{\partial\epsilon}{\partial\rho} \right)_T^2 |(\tilde{I} - \mathbf{e}_r \mathbf{e}_r) \cdot \boldsymbol{\epsilon}|^2 \langle \Delta\rho(\mathbf{Q}) \Delta\rho(-\mathbf{Q}) \rangle \quad [41]$$

where $\boldsymbol{\epsilon}$ is the unit polarization vector of the incident beam. The time average $\langle \Delta\rho(\mathbf{Q}) \Delta\rho(-\mathbf{Q}) \rangle$ is statistically equivalent to an ensemble average. Since the number density can be expressed as a sum of delta functions, i.e.

$$\rho(\mathbf{r}') = \sum_{l=1}^N \delta[\mathbf{r}' - \mathbf{R}_l] \quad [42]$$

its Fourier transform is simply

$$\rho(\mathbf{Q}) = \sum_{l=1}^N \exp[i\mathbf{Q} \cdot \mathbf{R}_l] \quad [43]$$

so that

$$\Delta\rho(\mathbf{Q}) = \sum_{l=1}^N \exp[i\mathbf{Q} \cdot \mathbf{R}_l] - \bar{\rho} \delta(\mathbf{Q}) \quad [44]$$

Therefore, with the exception of forward scattering along the direction of the incident light ($\mathbf{Q} = 0$), the quantity $\Delta\rho(\mathbf{Q})$ may be replaced by $\rho(\mathbf{Q})$, and

$$\frac{1}{N} \langle \rho(\mathbf{Q}) \rho(-\mathbf{Q}) \rangle = \frac{1}{N} \left\langle \sum_{l,l'} \exp[-i\mathbf{Q} \cdot (\mathbf{R}_l - \mathbf{R}_{l'})] \right\rangle \quad [45]$$

The latter expression is identical to that of the static structure factor $S(\mathbf{Q})$ previously identified in the quantum derivation. Thus, the cross-section $d\sigma/d\Omega$, is again given by $N(d\sigma/d\Omega)_0 S(\mathbf{Q})$, except the basic unit of scattering from the system is now

$$\left(\frac{d\sigma}{d\Omega} \right)_0 = \frac{k_v^4}{(4\pi\epsilon_0)^2} \left(\frac{\partial\epsilon}{\partial\rho} \right)_T^2 |(\tilde{I} - \mathbf{e}_r \mathbf{e}_r) \cdot \boldsymbol{\epsilon}|^2 \quad [46]$$

The double-differential cross-section is developed in the same way as before, and the result is identical to the expression given by eqn [25], which again involves the dynamic structure factor $S(\mathbf{Q}, \omega)$. The latter can now also be written in terms of correlations involving Fourier

components of the density fluctuations:

$$S(\mathbf{Q}, \omega) = \frac{1}{2\pi N} \int_{-\infty}^{+\infty} dt \exp[-i\omega t] \times \langle \rho(-\mathbf{Q}, 0) \rho(\mathbf{Q}, t) \rangle \quad [47]$$

Role of Dynamic Structure Factors in Spectroscopy

For light scattering, both the quantum and classical derivations of the double-differential cross-section result in an expression that is the product of $(d\sigma/d\Omega)_0$ and the dynamic structure factor, $S(\mathbf{Q}, \omega)$. This decomposition of $d^2\sigma/d\Omega d\omega$ into two factors, the first being the angular cross-section from a single scattering unit and the second representing space and time-dependent structure within the system, is what makes the radiation useful as a spectroscopic tool. This separation occurs whenever the radiation couples weakly to the scattering medium. For example, the scattering of X-rays and thermal neutrons fall into this category. X-rays interact with the atomic electrons, and the basic scattering unit involves the classical electron radius $r_0 = (e^2/mc^2)/4\pi\epsilon_0$ (e and m are the electron's charge and mass, respectively) and

$$\left(\frac{d\sigma}{d\Omega}\right)_0 = r_0^2 |\epsilon_{k\lambda} \cdot \epsilon_{k'\lambda'}|^2 \left(\frac{k'}{k}\right)^2 \quad [48]$$

The scattering of thermal neutrons occurs because of the interaction between the neutrons and the atomic nuclei of the target. The basic scattering unit in this case is given by

$$\left(\frac{d\sigma}{d\Omega}\right)_0 = b^2 \left(\frac{k'}{k}\right)^2 \quad [49]$$

where b is called the bound scattering length of an atomic nucleus.

The dynamic structure factor is a function of the two parameters $\mathbf{Q}$ and ω . Loosely speaking when the radiation imparts a momentum $\hbar\mathbf{Q}$ and an energy $\hbar\omega$ to the system, it, in effect, probes the structure and dynamics of the system with a spatial resolution of Q^{-1} and a

temporal resolution of ω^{-1} . **Table 1** shows the regions of (Q, ω) -space and the corresponding resolutions in real-space and real-time accessible to photon and neutron spectroscopies using current instrumentation and measurement techniques.

One often expresses the dynamic structure factor in the form

$$S(\mathbf{Q}, \omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} dt \exp[-i\omega t] F(\mathbf{Q}, t) \quad [50]$$

with

$$F(\mathbf{Q}, t) = \left\langle \frac{1}{N} \sum_{i,j} \exp[-i\mathbf{Q} \cdot \mathbf{R}_i(0)] \exp[i\mathbf{Q} \cdot \mathbf{R}_j(t)] \right\rangle \quad [51]$$

$F(\mathbf{Q}, t)$ is known as the intermediate scattering function. The dynamic structure factor is just the temporal Fourier transform of $F(\mathbf{Q}, t)$. For scattering measurements that involve the frequency, or energy, domain, one determines $S(\mathbf{Q}, \omega)$ directly. Examples include optical mixing spectroscopy in light scattering, as well as crystal spectroscopy and time-of-flight measurements in the case of thermal neutron scattering. On the other hand, the intermediate scattering function is directly measured in the time domain. Both photon correlation spectroscopy and neutron spin-echo spectroscopy measure $F(\mathbf{Q}, t)$.

Detailed discussions of $S(\mathbf{Q}, \omega)$ and $F(\mathbf{Q}, t)$ for various target systems appear in the Further Reading section. To illustrate the type of information that is contained in these functions, consider the specific case of scattering from a fluid consisting of N identical, independently moving scattering centres (or particles). In this case, the scattering from the various particles adds incoherently and is determined by a simplified self-intermediate scattering function governed by the motion of a single particle:

$$F_S(\mathbf{Q}, t) = \langle \exp[-i\mathbf{Q} \cdot \mathbf{R}(0)] \exp[i\mathbf{Q} \cdot \mathbf{R}(t)] \rangle \quad [52]$$

The brackets represent a thermal average at temperature T .

From purely classical considerations, the scattering function always reduces, at least approximately, to the

Gaussian form

$$F_S^{\text{cl}}(\mathbf{Q}, t) = \exp\left[-\frac{1}{2}\mathbf{Q}^2 W(t)\right] \quad [53]$$

where $W(t)$ is a width function that corresponds to the mean-square displacement of the scattering particle as a function of time. The specific form of the width function depends on the type of motion exhibited by the particle. $W(t)$ for a particle (mass M) in an ideal gas ($V_0 = k_B T/M$) and for a diffusing particle (diffusion coefficient D) are given by

$$W(t) = \begin{cases} V_0^2 t^2 & \text{for ideal gas} \\ 2Dt & \text{for diffusing particle} \end{cases} \quad [54]$$

Figure 4 is a comparison of the behaviour of these functions, along with $W(t)$ for a particle moving through a typical liquid. Fourier transforming the $F_S^{\text{cl}}(\mathbf{Q}, t)$ s gives the corresponding forms for the (self) dynamic structure factors:

$$S_S^{\text{cl}}(\mathbf{Q}, \omega) = \begin{cases} (2\pi\mathbf{Q}^2 V_0^2)^{-1/2} \exp[-\omega^2/2V_0^2\mathbf{Q}^2] & \text{for ideal gas} \\ \frac{1}{\pi} \left[\frac{D\mathbf{Q}^2}{\omega^2 + (D\mathbf{Q}^2)^2} \right] & \text{for diffusing particle} \end{cases} \quad [55]$$

For a fixed value of $\mathbf{Q}$, the functions $S_S^{\text{cl}}(\mathbf{Q}, \omega)$ give the line shapes for the gas and diffusion cases to be Gaussian and Lorentzian, respectively.

The latter results neglect any quantum corrections to the self-intermediate scattering functions. In the case of the ideal gas, the full quantum-mechanical expression for $S_S(\mathbf{Q}, \omega)$ is obtained from the corresponding classical one simply by multiplying by two exponential factors, i.e.

$$S_S(\mathbf{Q}, \omega) = \exp[\hbar\omega/2k_B T] \exp[-\hbar^2\mathbf{Q}^2/8Mk_B T] S_S^{\text{cl}}(\mathbf{Q}, \omega) \quad [56]$$

The first factor, $\exp(\hbar\omega/2k_B T)$, is known as the ‘detailed balance factor’ – it produces an asymmetry in the quantum-mechanical structure factor, whereas the classical one is an even function of ω . The second factor, $\exp(-\hbar^2\mathbf{Q}^2/8Mk_B T)$, can also be written as $\exp(-E_R/4k_B T)$, where $E_R = \hbar^2\mathbf{Q}^2/2M$ is the recoil energy of the target particle. Hence this exponential factor is known as the recoil factor. Equation [56] is exactly true only in the ideal gas case; however, it is also approximately valid for other scattering systems as well.

Figure 4 Mean-square displacement function for a particle in an ideal gas, a diffusing particle, and a particle moving through a typical liquid.

Introduction

Secondary ion mass spectrometry (SIMS) is a desorption mass spectrometry (MS) technique. In SIMS, an energetic primary ion strikes a sample surface, leading to the ejection of secondary species – neutrals, positive and negative ions, and electrons. The ejected ions are extracted and detected using a mass analyzer. The majority of the emitted species are neutrals that can be detected using postionization techniques (secondary neutral mass spectrometry (SNMS)).

Early SIMS spectra consisted of fragment ions and were used for the elemental analysis of surfaces. Indeed, for many years SIMS has been used to obtain accurate atomic distributions as a function of depth in a sample – commonly termed ‘depth profiles’ – and is a standard technique used in the semiconductor industry as well as in the analysis of geological and astronomical samples. **Figure 1** displays an example of a depth profile: the

distribution of Ni^+ , Cr^+ , and Si^+ with depth for a Ni/Cr/Si(100) sample.

In the late 1960s, Benninghoven and coworkers developed a single-ion counting technique for MS, allowing SIMS spectra to be obtained under low ion beam currents (‘static’ SIMS). Under these conditions, the sample is softly ionized, making it possible to desorb intact molecular ions. Static SIMS has since been largely overshadowed by other MS techniques, including electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI). This is because in SIMS it was difficult to desorb ions with $m/z > 500$, which made the detection of large molecules very hard. Recently, SIMS has undergone a renaissance with the development of commercially available cluster ion sources, which are easy to use and have long lifetimes. Cluster ion beams generate secondary ions (SIs) with much higher efficiencies than atomic primary ion beams, leading to greatly increased SI yields and decreased sample damage. This has led to improvements in 2-D MS imaging, the ability to obtain molecular depth profiles, and the development of 3-D MS imaging.

Imaging Mass Spectrometry

MS is not normally thought of as an imaging technique. However, almost 50 years ago it was proposed that an ion optical collection system could be built that preserved the spatial relationship between a sample and a detector, in a similar manner to an optical microscope. Indeed, the ion microscope has since become a commercial instrument and is used in many fields, from archaeometry to materials science.

A second imaging instrument is the ion microprobe. In this instrument, the primary ion beam is moved (rastered) across the sample surface, and an image built up from the mass spectra acquired at each pixel, in a similar manner to the way a television image is produced. **Figure 2** displays an MS image of a mouse brain slice on a stainless steel plate obtained using an ion microprobe. In ion microprobes, liquid metal ion guns (LMIGs) can be employed, which can focus the ion beam to ~ 50 nm diameter and thus produce a very high lateral resolution chemical image. To analyze a wide mass range while keeping the primary ion dose low, time-of-flight (TOF) analyzers are generally employed. This instrument configuration is called time-of-flight secondary ion mass spectrometry (TOF SIMS). TOF SIMS has a lateral

resolution of $\sim 150 \text{ nm}$ and can detect molecular ions up to several thousand atomic mass units.

Basic Principles of SIMS

The formation of SIs by an ion incident on a sample is a complex process. In general, when a high-energy beam of ions (e.g., Ga^+) strikes a sample, the kinetic energy is transferred to the solid causing a collision cascade in the sample. Some of the collisions return to the surface, resulting in the ejection of atoms and clusters from the sample. Some of these ejected particles are ionized in the process of leaving the surface. The point of emission of secondary particles can be several nanometers away from the point of primary ion impact, and so the final collision results in emission of secondary particles with low energy

($\leq 20 \text{ eV}$). Over 95% of the SIs and neutrals emitted originate in the top several layers of the material. For large cluster ions (e.g., C_{60}^+), the sputtering mechanism appears to be different. In this case, molecular dynamics simulations indicate that a crater forms several nanometers deep, from which material is sputtered.

The type of SIs formed strongly depends on the properties of the primary ion including its composition, current density, and energy. Since ionization and emission of ions occurs from the top layers of the sample, the SI yield is strongly influenced by the electronic state of the substrate. Hence, the SI current is dependent on a number of variables:

$$I_m^\pm = I_p Y_m \eta^\pm \alpha^\pm \theta_m$$

where $I_m^\pm$ is the SI current of species m , I_p is the primary ion current, Y_m is the sputter yield of m , $\eta^\pm$ is the

ion transmission efficiency for positive (+) or negative (−) ions, $\alpha^\pm$ is the ionization probability of m , and θ_m is the fractional surface concentration of m .

The sputter yield, Y_m , is determined by the primary ion flux, charge, energy and mass, and the chemical environment within the sample. The yield increases linearly with flux but nonlinearly with charge, energy, and mass. The transmission efficiency, $\eta^\pm$, is determined by the physics of the sputtering process and the characteristics of the mass spectrometer, and varies between $\sim 10^{-4}$ and 0.5.

The chemical nature, crystallinity, and topography of the sample also affect the SI yield. The ionization probability, $\alpha^\pm$, can vary by several orders of magnitude, from $\sim 10^{-5}$ to 0.1, depending on the species involved and the chemical environment.

Instrumentation

There are many different instrument configurations used in SIMS. Depth profiling and imaging of semiconductors and organic samples require different primary ion and mass analyzer properties. Primary ions employed include Ga^+ , In^+ , O_2^+ , Cs^+ , Au_n^+ ($n=1-7$), C_{60}^{x+} ($x=1-3$), SF_5^+ , and Bi_n^{x+} ($n=1-6$; $x=1,2$). In an SIMS microprobe imaging experiment, an incident ion beam is focused to a probe size of $\sim 10-200$ nm. The masses of the desorbed ions are determined with TOF, magnetic sector, or quadrupole mass analyzers. The size of the ion dose determines whether a dynamic or static SIMS experiment is performed. MS imaging using an ion microscope is normally performed under dynamic SIMS conditions.

In a static SIMS experiment, the number of primary ions incident on the surface is at least two orders of magnitude smaller than the number of surface atoms. The number of surface atoms is $\sim 10^{15}$ atoms cm^{-2} , and so the static limit is 10^{13} ions cm^{-2} . Chemical damage is not normally observed because each incident primary ion has a high probability of striking an undisturbed part of the surface. In contrast, in dynamic SIMS the number of primary ions exceeds the number of surface atoms, eroding the sample due to sputtering and chemical damage. For a typical ion beam current of 1 nA striking a $50 \mu\text{m}^2$ area, the erosion rate is a few micrometers per minute. In this regime, by obtaining mass spectra as a function of time, elemental and molecular depth profiles can be obtained.

Primary Ion Sources

There are a number of issues that need to be considered when choosing a primary ion beam including the type of SIMS experiment and the sample damage caused by a single primary ion impact.

Atomic Ion Sources

In dynamic SIMS the most commonly used primary ion is Cs^+ , particularly for imaging. In a Cs^+ source primary ions are generated by surface ionization from a macroscopic Cs substrate, extracted through apertures and focused onto the sample. These sources produce a high-quality focused ion beam with ~ 200 nm diameter. Other primary ions used in dynamic SIMS imaging include O_2^+ and Ar^+ . These have characteristics similar to Cs^+ and are generated in duoplasmatron sources. Both O_2^+ and Cs^+ are chemically reactive; these ions create either electronegative or electropositive surface species that retain their charge during desorption. Thus, O_2^+ ions enhance positive ion creation, whereas Cs^+ enhances negative ion formation.

Until ~ 2005 , the ion source most commonly used in static SIMS imaging was the Ga^+ LMIG because it provided the smallest probe size (~ 10 nm) and the highest current density (brightness) ($1-10$ A cm^{-2}). Today, Ga^+ LMIGs have been supplanted by Bi_n^{x+} and Au_n^+ LMIGs. In an LMIG, the source is a field emitter coated with the required metal. A high electric field extracts metal ions from the tip via the formation of a Taylor cone, and the ions are focused onto the sample using ion optics. The smallest beam diameters ($10-100$ nm) are usually achieved in the energy range $10-60$ keV.

The major disadvantage of Ga LMIGs is that Ga^+ ions are relatively poor at generating molecular and other heavy SIs ($m/z \geq 500$). This results in image resolutions of $< 1 \mu\text{m}$ because in SIMS both the ion beam diameter and the SI yields determine the image resolution. This is because Ga^+ ions are not particularly reactive and so do not generate electronegative or electropositive species at the sample surface, which increase the SI yield. Ga^+ primary ions are also not particularly efficient at desorbing molecular ions because they penetrate deep into the sample rather than deposit energy into the near-surface region.

Recent developments in LMIGs have concentrated on improving molecular yields using new ion sources. In all cases, the primary ion beams have a larger diameter than the Ga^+ LMIG. However, the images obtained have higher lateral resolutions because a smaller primary ion dose is needed to obtain the same number of SIs per pixel. One of the first ion sources to improve SI yields was the In^+ LMIG. The mass difference is large enough between In and Ga that molecular SI yields are four to five times greater for In^+ primary ions than for Ga^+ . However, In^+ LMIGs have several disadvantages: the tips are more prone to oxidation than Ga, isotopically pure emitters are required for high-mass resolution applications, and it is difficult to produce ion beams with diameters < 100 nm.

Gold LMIGs have been used in SIMS since the early 1990s. Early designs had short lifetimes because high

source temperatures were required for Au to wet the emitter tip. Later, AuGe and AuSi eutectic alloys were introduced that allowed much lower source temperatures to be employed, greatly increasing tip lifetimes. More recently, Bi LMIGs were introduced. Both Bi^+ and Au^+ primary ions have similar SI yields, typically 10–100 times larger than for Ga^+ . However, the major use of Au and Bi LMIGs is in the generation of cluster primary ions.

Cluster Ion Sources

Polyatomic primary ions greatly increase molecular SI yields when compared to monoatomic primary ions. Cluster ion beams employed in SIMS include $(\text{CsI})_n\text{Cs}^+$, $(\text{Bi}_2\text{O}_3)\text{BiO}^+$, SF_5^+ , Au_n^+ , Au_n^- , Bi_n^{x+} , and C_{60}^{x+} . The SF_5^+ , Au_n^+ , Bi_n^{x+} , and C_{60}^{x+} primary ion sources are commercially available.

The use of cluster ion sources for SIMS and sputtering has been investigated since the 1960s. Early studies demonstrated that diatomic and triatomic P, As, Sb, and Bi primary ions greatly increased sputtering yields, and the yields were strongly nonlinear with the number of atoms in the primary ion ('nonlinear yield enhancement'). Later experiments using polymer and molecular overlayers showed that the yield enhancement occurred without a simultaneous increase in the damage cross-section. (The damage cross-section is the average area damaged by a single primary ion impact, i.e., the sample area modified in such a way that the considered SI cannot be created at a later time.)

Early polyatomic primary ion sources were often difficult to maintain, had short lifetimes and low beam currents could not be focused to small spot sizes. The development of Au_n^+ , Bi_n^{x+} , and C_{60}^{x+} primary ion sources has resolved many of these issues. Au_n^+ and Bi_n^{x+} sources can be focused to a small spot size (~ 100 nm), and have long lifetimes (≥ 500 $\mu\text{A h}$) and high brightness. These sources emit a variety of ions and so a mass filter is employed to select the desired primary ion. Bi_n^{x+} ion sources produce higher cluster currents than Au_n^+ sources because a eutectic alloy is not required to lower the source operating temperature.

In a C_{60}^{x+} ion source, a C_{60} vapor is ionized by electron impact, generating C_{60}^+ , C_{60}^{2+} , and C_{60}^{3+} ions. The desired primary ion is selected using a mass gate. The C_{60}^{x+} ions are then focused to an ~ 1 - μm beam diameter, which is larger than the spot size for Au_n^+ and Bi_n^{x+} sources. The C_{60} ion source has a long lifetime (~ 500 $\mu\text{A h}$) before it requires cleaning.

Bi, Au, and C_{60} ion sources can be used to obtain high-mass molecular ion ($m/z \geq 500$) images from a variety of samples, including tissues, single cells, organic/molecular electronics, and chip-based molecular arrays. Polyatomic primary ion sources can also be employed to

obtain molecular depth profiles with very high-depth resolution (~ 3 nm for some samples). In general, it appears that C_{60}^+ and SF_5^+ are the most amenable primary ions for depth profiling.

Mass Analyzers

There are three types of mass analyzer commonly used in SIMS: TOF, quadrupole (QMA/QMS), and double-focusing mass sector. To obtain elemental depth profiles, quadrupole and magnetic sector mass analyzers are used. For a QMA, the mass resolution is limited to ~ 1 u so it may not be able to resolve the appropriate dopant/impurity mass. However, its major advantage is that it can be placed at a considerable distance from the target, which allows large samples (e.g., 6 in. Si wafers) to be analyzed. Early dynamic and static imaging SIMS experiments both employed QMAs. This was because QMAs are ultrahigh vacuum compatible, have high transmission, and are relatively insensitive to the SI kinetic energy. However, QMAs have a limited mass range, and so were found to be too restrictive.

Magnetic sector instruments are widely used because they have very high-mass resolving power and SI transmission. Their main disadvantages are that the ion extraction geometry prevents the analysis of large sample areas, and that the number of masses that can be analyzed simultaneously is restricted. Double-focusing magnetic sector mass analyzers are commercially available in the Cameca series of microprobes (lateral resolution: < 50 – 150 nm) and microscopes (lateral resolution: ~ 1 μm). Mass resolving powers of 25 000 have been reported for the Cameca 7f.

TOF instruments combine the high transmission and mass resolution capabilities of the magnetic sector analyzer and the multiplexing abilities of QMAs. In a TOF configuration, the incident primary ions strike the sample as a short pulse. Desorbed molecules are accelerated to a specific energy (typically 2 keV) and then allowed to drift through a fixed distance ('field free' region). Since the kinetic energy of the ions is known, the ion arrival times can be used to determine their mass. The major advantage of a TOF mass analyzer is its multiplexing capability; all desorbed ions with differing mass and flight times are sequentially detected. A second advantage is that the design of a TOF is relatively simple. Today, TOF SIMS instruments are the preferred design for static SIMS measurements and molecular depth profiling.

One problem with TOF analyzers is uncertainty in the measurement of the ion flight time. There are many sources of this, including uncertainties in SI creation time and kinetic energy. Today, primary ion pulses < 1 ns duration can be produced, while maintaining ~ 100 nm

beam diameter, reducing the uncertainty in the ion creation time. By using time-to-digital converters (TDCs), the flight times of molecular ions can be measured to very high precision. For example, an ion m/z 100 and energy 2 keV that drifts through 3 m has a flight time of $\sim 48 \mu\text{s}$. Using a TDC, the SI flight time can be determined within 200 ps and thus time resolutions of greater than one part in 235 000 can be achieved.

The energy spread of ions desorbing from a surface is several electron volts, which causes uncertainty in the mass determination. To compensate for the energy spread, two instrument designs are generally used. The first is the high-performance 'reflectron' TOF configuration and is commercially available in the ION TOF series of instruments. In this geometry, SIs are reflected at the top of a flight tube such that slower ions have a shorter flight path than faster ones. If the acceleration/deceleration voltages are correctly adjusted, mass resolutions of greater than 10 000 can be achieved. The second type of instrument employs three electric sectors to focus ions of the same mass but slightly different energy to the detector position. The 'TRIFT' analyzer has similar specifications to the reflectron configuration, but can be used in both ion microscope and microprobe configurations. TRIFT design instruments are also commercially available (Physical Electronics Inc.).

Postionization and Sensitivity Enhancement: SNMS

Approximately 95% of sputtered species are neutrals, and so SIMS ignores a large amount of chemical information from the surface. By detecting desorbed neutrals, it is possible to enhance the sensitivity of SIMS. This is important for high lateral resolution MS imaging because the number of analyte molecules is the limiting factor, rather than the probe size. Similarly, in dynamic SIMS the sensitivity is determined by the number of analyte molecules in a given volume. A second motivation for analyzing sputtered neutrals is that the ionization and sputtering processes are decoupled, making it easier to obtain quantitative data.

There are two approaches to postionizing desorbed neutrals: electron and laser irradiation. In electron postionization, an electron beam or low-pressure plasma is directed through the desorbing flux. Typical useful yields (defined as the ratio of detected ions to sputtered ions) are 10^{-6} , an ~ 100 -fold improvement over SIMS.

Laser postionization greatly increases the ionization efficiency, with typical useful yields of 10^{-3} . The laser irradiation photoionizes the desorbed neutral flux above the sample surface. However, this is not a generally applicable technique because it must be optimized for each sample to minimize photoinduced fragmentation.

Postionization schemes to maximize the number of neutrals detected include resonance-enhanced and non-resonant multiphoton ionization (REMPI and NREMPI), and single-photon ionization (SPI). In REMPI two, or more, photons of specific wavelength are combined to match the electronic absorption properties of the desorbed neutrals. In this method, the laser power is increased until the electronic transitions are saturated to try to achieve 100% ionization efficiency. Detection thresholds of 4×10^6 molecules have been reported, but only one species can be detected at a time. To simultaneously analyze all the desorbing chemical species NREMPI is employed. In this experiment, multiple high-energy photons are used to nonselectively ionize desorbing molecules, which require that the laser be tightly focused above the sample surface. For NREMPI, detection thresholds are higher, $\sim 10^9$ molecules.

Similar to NREMPI, SPI is a nonselective detection method and uses a coherent vacuum ultraviolet (VUV) laser. It is considered to be a 'soft' ionization technique because efficient ionization occurs at low light intensities, and so multiphoton absorption is unlikely. Since only one photon is absorbed, photofragmentation is greatly reduced. Further, the ionization cross-sections are more uniform, resulting in more quantitative detection probabilities.

Ultrashort laser pulses have been used in postionization experiments since the 1990s. Pulses of < 500 fs duration greatly enhance molecular ion intensities and greatly reduce photofragmentation. Femtosecond lasers can also be pulsed at 1 kHz allowing rapid data acquisition, which is important for imaging MS.

Matrix-Enhanced SIMS

Molecular ion yields are dependent on many factors including the matrix surrounding the molecule of interest. There have therefore been many studies of how molecular ion yields can be increased by dissolving the analyte in a matrix.

It was demonstrated over 30 years ago that molecular ion signals could be increased by either acidification (increasing $[M + H]^+$) or treating the sample with a base (increasing $[M - H]^-$). Matrices employed to enhance SIMS ion intensities have since included ammonium chloride and common MALDI matrices such as 2,5-dihydroxybenzoic acid. Gold and silver films and nanoparticles also enhance molecular ion yields (meta-SIMS). With these methods, quasimolecular ions from proteins up to m/z 10 000 have been detected.

At present, the mechanism of matrix-enhanced SIMS (ME SIMS) is not well understood but is certainly very different to MALDI. The major mechanism of SI enhancement appears to be the donation of protons from the matrix to analyte molecules.

Data Analysis

One challenge for SIMS is the quantitative analysis of the chemical components in a sample. This is because the ion intensities are complex functions of matrix chemistry, sample topography, instrument transmission, and detector response. Further, the signal intensity is not a linear combination of these factors. There are two methods commonly employed to quantify SIMS data. Relative sensitivity factors (RSFs) are ratios of the analyte intensity to the intensity of a reference species of known concentration in a given matrix. A second method is to use standards of known concentration to create calibration curves, but good standards are not always readily available, particularly for biological materials, and are often hard to prepare.

SIMS data are also inherently multivariate: for a dynamic SIMS experiment, the depth profile is a composite of mass spectra collected from each level in the sample. In a static SIMS experiment, the mass spectrum is a composite of mass spectra from each species present in the uppermost 10–20 Å of the sample. An image is a composite of mass spectra from each pixel (or voxel), and it also contains topographic information. In addition, a relatively large ion beam width leads to a ‘blurring’ and loss of lateral resolution. Thus, composition changes in multicomponent samples can be hard to follow. Chemometric methods such as principal component analysis (PCA) and partial least squares (PLS) have been employed to extract information from SIMS data. Other data-reduction and imaging-processing methods have also been used to analyze SIMS data, including pattern recognition techniques such as neural networks and maximum entropy methods.

Recent Developments (2009)

The unique properties of cluster primary ion sources – enhanced high-mass SI yields, greatly reduced accumulated sample damage, and relatively flat sputter crater bottoms – have led to the development of 3-D molecular MS imaging. In this method, a 2-D image of the sample is obtained, the sample is then sputtered (eroded) using a cluster ion beam, another 2-D image is obtained, and so on, to build up a 3-D volumetric image. **Figure 3** displays an example of a 3-D SIMS image: the volumetric distribution of m/z 152, a characteristic ion for acetaminophen, through a poly(lactic) acid (PLA) film created from a series of 74 SI images. Three-dimensional molecular MS imaging requires that the damage created by the primary ion beam is removed faster than it is created, which is often the case for polyatomic ion beams, in particular C_{60}^+ . To date, there have only been a few demonstrations of 3-D SIMS analysis of biological or organic samples. These studies have employed the same ion beam (C_{60}^+ or SF_5^+) for both imaging and sputtering the sample. The imaging

Figure 3 Volumetric view of the distribution of m/z 152 from an acetaminophen-doped PLA polymer film. The view was created using a series of 74 secondary ion images with a 250 μm field of view and 10 s image acquisition. of nanotechnological devices or cells requires more highly focused ion beams, and so it seems likely that in the future 3-D molecular images will be produced by using Bi_n^{x+} or Au_n^+ ions to image the surface, and C_{60}^+ or SF_5^+ ion beams for the sputtering.

Two orthogonal MS/MS SIMS instruments are also being developed at this time, based on an AB Sciex Q-Star and the Ionoptika J105 Chemical Imager. These instruments have two advantages over traditional TOF SIMS instruments for 2-D and 3-D molecular imaging. In a TOF instrument, a pulsed primary ion beam is required to obtain good mass resolution; this leads to a low duty cycle and long acquisition times of hours, or even days, to obtain large chemical images. By using a dc primary ion beam in an orthogonal TOF, which decouples ionization and mass detection, the ion fluence is increased by up to four orders of magnitude that results in significantly higher SI signals (for sufficiently thick samples) and therefore reduced acquisition times. Tandem MS/MS experiments can be used for the effective identification of unknown compounds in complex multicomponent samples such as biological tissues and will be very powerful when combined with SIMS imaging.

The magnetic sector is the oldest type of mass analyser. Experiments initiated in 1906 by JJ Thompson demonstrated the different deflections of various ‘positive’ rays in superposed crossed magnetic and electric fields. In 1912, using this equipment, the isotopes of neon were discovered, and over the next decade magnetic sector instruments built separately by Aston and by Dempster were used to identify most of the isotopes and determine their relative abundance. In 1931 Bainbridge added a velocity filter to Dempster’s basic design to limit the energy distribution of ions entering the magnet. This refinement improved mass resolution and the relative mass measurement precision of the isotopes. This allowed the ‘packing fraction’ of the isotopes to be determined.

Industrial interest in mass spectrometry grew in the following decade and in 1942 the first commercial mass spectrometer, a magnetic sector instrument, was built by Consolidated Engineering Corporation and sold to the Atlantic Refining Company for the analysis of gasoline refining streams. Magnetic sector instruments are now only one of several different types of mass spectrometer

manufactured commercially. Nevertheless magnetic sector mass spectrometers are still used for a number of important applications, in particular in the areas of target compound trace analysis, accurate mass measurement, isotope ratio measurement and fundamental ion chemistry studies.

Principle of Operation

Ions with mass (*m*) and charge (*ze*) accelerated through an electrical potential difference (*V*) will have velocity (*v*) and kinetic energy (KE) where:

$$KE = zeV = \frac{1}{2}mv^2 \quad [1]$$

Ions with charge (*ze*) moving through a magnetic field (*B*) with velocity (*v*) are subject to the Lorentz force (*F*) orthogonal to the direction of the field and direction of travel. Consequently ions travel with a circular trajectory with radius (*r_m*) in which the centripetal force is provided by the Lorentz force:

$$F = B \quad ze \quad v = m(v^2/r_m) \quad [2]$$

Eliminating (*v*) from eqns [1 and 2]:

$$m/ze = B^2 r_m^2 / 2V \quad [3]$$

In the SI system of units for *B* (tesla), *r_m* (metres), *V* (volts) and *m/z* (daltons per unit of electronic charge) eqn [3] becomes:

$$m/z = 4.786 \times 10^7 \cdot B^2 r_m^2 / V \quad [4]$$

In its simplest form, the mass spectrometer transmits ions of a particular mass and charge from source to detector via a circular trajectory through a magnetic sector. Here the magnetic sector is a mass filter, and a mass spectrum can be recorded by scanning the magnetic field or accelerating voltage with serial detection of mass peaks. Alternatively, several detectors may simultaneously record several different ion masses, each taking a different trajectory. This principle may be extended to incorporate a continuous detector array in which a complete portion of the mass spectrum is recorded simultaneously. The magnet sector is usually constructed from a laminated iron-cored electromagnet with low inductance coils to allow fast scanning or switching.

Superconducting magnets are not appropriate since they are not readily scanned. However, permanent magnets may be used for certain dedicated applications such as isotope ratio determinations.

Optics

An ion moving in a magnetic field is dispersed with respect to its momentum (ρ). The momentum of an ion is given by:

$$\rho = mv = (2m \cdot KE)^{1/2} \quad [5]$$

Therefore ions with the same kinetic energy (KE) are, in effect, dispersed with respect to their mass. In addition, the shape of the magnetic sector can be designed to have ion directional focusing properties. A magnetic sector of a particular shape and size will have a particular combination of ion dispersion and directional focusing characteristics.

Single Focusing

An arrangement which combines an ion source with an ion beam width defining slit, a magnetic sector with convergent directional focusing characteristics and an ion 'collector' slit positioned at the image point of the source slit is defined as single focusing. The magnetic sector directional focusing characteristics can be designed to a very high order, but its imaging properties will be limited by any spread in ion energy. Consequently such instruments are used where the energy spread of ions is low, for example with an electron impact ionization source, and where a high resolution is not required (Figure 1).

Stigmatic Focusing

An inhomogeneous magnetic field has field components in more than one direction. If the magnetic field is inhomogeneous the focusing in the direction of dispersion is modified, and focusing in the direction orthogonal to the direction of dispersion is introduced. As the focal power in the direction of dispersion reduces, the focal power in the direction orthogonal to that increases, and

Figure 1 Single-focusing magnetic sector, with focusing in the 'Y' direction only.

when the focal power in these two directions becomes the same the sector has stigmatic focusing. This can provide more efficient ion transmission from source to detector, although higher order focusing terms in the direction of dispersion are usually compromised and ultimate resolution reduced.

A homogeneous magnetic field in which the shape of the sector has been designed to have non-normal ion entry and/or ion exit will also modify focusing in the direction of dispersion and introduce focusing in the orthogonal direction. In a similar way such a magnetic sector can be designed to provide stigmatic focusing (Figure 2).

Mass Dispersion and Resolution

The mass dispersion coefficient (D_m) of a single-focusing magnetic sector is proportional to the radius of curvature (r_m) of the ion beam trajectory in the magnetic field. The spatial separation (y) of two similar masses with mean mass (m) and mass difference (Δm) is related to the mass dispersion coefficient by:

$$y = D_m \cdot \Delta m / m \quad [6]$$

The ion beam width (w_b) at the image position is related to the ion beam width defined by the source slit (w_s), the image lateral magnification (M) and the sum of the imaging aberration coefficients (α) by:

$$w_b = M \cdot w_s + \alpha \cdot r_m \quad [7]$$

The mass resolving power ($m/\Delta m$) for a 'collector' slit width (w_c) is given by:

$$m/\Delta m = D_m / (w_b + w_c) = D_m / (M \cdot w_m + w_c + \alpha \cdot r_m) \quad [8]$$

Figure 2 Single-focusing magnetic sector, with stigmatic focusing in 'Y' and 'Z' directions.

Thus, the mass dispersion coefficient and the slit widths are the most significant parameters in setting the resolution, and the ratio of dispersion to magnification (D_m/M) is a key figure of merit in the design of an instrument. However, ultimate resolution is limited by the imaging aberrations.

Double Focusing

It has been pointed out that the magnetic sector will disperse ions with respect to their momentum, and hence with respect to their mass if they are monoenergetic. However, ions will normally have a spread in kinetic energy, depending on the nature of the ion source, and this will broaden the image width. This usually becomes the limiting factor to achieving high resolution.

Momentum dispersion may be considered a combination of mass dispersion and energy dispersion. An electric sector will only disperse ions with respect to their energy, and so if an electric sector is combined with a magnetic sector the overall energy dispersion will be modified. A combination of magnetic sector and electric sector, which is directional focusing and in which the overall energy dispersion is zero, is said to be double focusing. Such a combination does not suffer the same image broadening due to spread in ion kinetic energy, and can achieve much higher resolution.

If the first sector has energy dispersion D_{e1} , and the second sector has energy dispersion D_{e2} , and image magnification of the second sector is M_2 , then the overall energy dispersion (D_e) is

$$D_e = M_2 \cdot D_{e1} + D_{e2} = 0 \quad [9]$$

If the electric sector precedes the magnetic sector, the double-focusing arrangement is said to be 'forward' geometry, and 'reverse' geometry if the electric sector follows the magnetic. Either arrangement is equally effective as a double-focusing optical system. However, the electric sector can provide additional benefits, which are different for each 'geometry'.

Forward geometry

Here the electric sector, which precedes the magnetic sector, can be used to further advantage if designed to have a lateral magnification less than unity. This will increase the dispersion to magnification ratio (D_m/M) and the source slit will be larger than it otherwise would have been to achieve a required resolution. The larger source slit usually results in higher transmission and reduced susceptibility to contamination.

Reverse geometry

Here the electric sector follows the magnetic sector, and therefore can no longer be used to increase the

dispersion-to-magnification ratio. However, the electric sector can now be used as an energy filter to prevent transmission of ions with very different energies – such as the product ions from metastable ion decompositions. In a single-focusing system, or a 'forward' geometry double-focusing arrangement, these product ions appear as defocused artefact peaks in the spectrum when they are generated in the field-free region before the magnetic sector. If the decompositions occur in the magnetic field, this usually results in an increase in background noise in the spectrum. In the 'reverse' geometry arrangement these are removed by the electric sector. The electric sector can also be used to further advantage by providing a means of analysing products from metastable ions resulting from ion decompositions in the field-free region between the magnetic and electric sectors. This type of analysis is considered in more detail in the Metastable ion analysis section.

Split forward and reverse geometry

Here the electric sector is divided into two smaller electric sectors, positioned before and after the magnetic sector. Each electric sector can be smaller than the single electric sector in a 'forward' or 'reverse' geometry, and provided the overall energy dispersion is zero, the arrangement can still be double focusing. This arrangement can benefit both from an increased dispersion-to-magnification ratio, by appropriate design of the first electric sector, and from removal of artefact peaks and background noise – resulting from metastable ion decompositions – by virtue of the second electric sector. Again the final electric sector can provide the means for directly analysing the products from metastable ions dissociating in the field-free region immediately preceding that electric sector (Figure 3).

Parallel Detection

Unlike the quadrupole type of mass filter, a magnetic sector may be designed to record the signal from several different masses simultaneously. This is referred to as parallel detection.

Multiple Collectors

Parallel detection provides a means of accurately recording the relative abundance of two or more different masses, since measurement of the ratio of these peak intensities is not susceptible to fluctuations or drift in the ionization source, or to rapidly changing sample concentration such as encountered in chromatography. Magnetic sector mass spectrometers designed to simultaneously transmit a number of different masses, each with a different trajectory, and incorporating multiple discrete detectors, are used to make the most accurate

Figure 3 Modified 'Nier-Johnson'-type double-focusing magnetic sector mass spectrometer (a) with 'forward' geometry, (b) with 'reverse' geometry, (c) with split 'forward' and 'reverse' geometry.

isotope ratio determinations. Instruments designed specifically for accurate isotope ratio determinations have included combinations of up to 16 Faraday and/or ion counting detectors, and isotope ratios may be determined to a precision of better than 10 ppm using such equipment.

Continuous Array Detectors

A magnetic sector mass spectrometer with a single detector may be used to record a mass spectrum by scanning and sequentially detecting mass peaks. The duty cycle for recording each mass in the spectrum is generally poor, and the higher the resolution or the wider the mass range the poorer the duty cycle. An array detector allows simultaneous acquisition over a range of masses thereby improving the duty cycle when used to record a spectrum. Array detectors employing high-density arrays of discrete charge-sensitive detectors or 'single ion' position sensitive detectors are very sensitive, although

Figure 4 Modified 'Mattauch-Herzog'-type double-focusing magnetic sector with flat focal plane.

they are usually limited in size. This imposes a limit on the combination of mass resolution and mass range of simultaneous detection. For example, an array of 2048 discrete detectors can be arranged to simultaneously detect ions over a 10% mass range with a resolution of ~ 4000 (FWHM). A 'single ion' position-sensitive detector simultaneously recording over a similar mass range may achieve approximately twice that resolution, but cannot cope with two ions arriving within one measurement period. This imposes an upper limit on the total ion current onto the detector of between 10^5 and 10^6 ions/s, which in turn imposes a limit on the practical mass range for simultaneous detection.

Alternatively, a large-scale photosensitive emulsion plate detector may be used to simultaneously record a large mass range with acceptable mass resolution. Such detectors require the mass spectrometer design to allow simultaneous transmission of a wide range of masses and focusing on to a flat plane. The double-focusing arrangement first described by Mattauch and Herzog in 1934 gives first-order double focusing over the entire length of the 'photo-plate'. Mass spectrometers based on this theory have been constructed to successfully record ions simultaneously over a 60:1 mass ratio (**Figure 4**).

High Resolution

The combination of magnetic and electric sectors to form a double-focusing arrangement includes sufficient degrees of freedom in the choice of design to allow higher order focusing to be achieved. A design constructed by Nier and Roberts in 1951, consisting of a 90° electric sector and 60° magnetic sector, arranged sequentially in a C-shaped geometry, was shown by Nier and Johnson to have first-order energy focusing and second-order directional focusing. Many modern designs of double-focusing instruments, in which all second-order directional- and energy-focusing terms are either zero or near zero, are essentially variations of the 'Nier-Johnson' geometry. Commercially manufactured instruments of this type achieve resolving powers in excess of 150 000 by the 10% valley definition (based on peak width at 5% height) or in excess of 350 000 by the FWHM definition

Figure 5 Doublet from PFTBA and FOMBLIN showing a resolving power of 200 000 (10% valley definition), or 450 000 (full width at half height definition).

(based on peak width at 50% height). They are used in particular in the petroleum industry for characterization of complex oil mixtures (Figure 5).

Accurate Mass Measurement

The capacity for high resolution enables double-focusing magnetic sector mass spectrometers to be used for accurate mass measurement. Accurate mass is always determined by reference to one or more known masses simultaneously introduced into the mass spectrometer, and there are two different methods in common use.

Peak Matching

This is the simplest and generally most accurate method of measuring the mass of a single peak. Here the magnetic field strength is held constant and the electric sector field and all other voltages are switched together such as to transmit in turn the known and unknown mass peaks. The difference between the two masses, ideally, is small. A narrow voltage scan is applied as each mass is selected

to display the peak profile, and the voltages are adjusted until the two peak profiles are exactly superimposed. The unknown mass is calculated from the ratio of the two voltage settings and the known reference mass. A refinement of this method entails the use of two known reference masses, preferably 'bracketing' the unknown mass, and adjusting the switched voltages until all three peak profiles are exactly superimposed. This allows correction for certain instrumental offsets, and a mass accuracy of better than 1 ppm is routinely achievable.

Alternatively voltage scanning through each of the three mass peaks while measuring the peak profiles with a high sampling rate analogue-to-digital converter, and computing the 'centre of mass' of each peak profile, will yield a similar mass measurement accuracy.

Magnetic Scanning

The 'peak matching' method is not appropriate if it is required to quickly measure the mass of a large number of peaks over a wide mass range. Here it is more appropriate to scan the magnetic field instead. However, the magnetic field strength from an iron-cored magnet is difficult to scan precisely. Consequently, a reference mixture is simultaneously introduced into the ion source such as to give a large number of known reference mass peaks at regular intervals throughout the mass range of interest. It is important that these mass peaks do not 'interfere' with any other mass peaks in the spectrum. The known and unknown masses are 'digitized' and recorded into a data system, and from each peak centre the accurate mass of the unknown peaks may be calculated. Perfluorokerosene (PFK) is commonly used as a 'reference mixture' since its 'electron impact' spectrum exhibits peaks every 12 or 14 daltons from m/z 31 to beyond m/z 800. Furthermore, the peaks are mass deficient and may easily be resolved from most other organic compounds. This method can yield an average mass measurement accuracy of about 1 milli-dalton over this mass range.

High-Resolution Selective Ion Recording

A double-focusing magnetic sector mass spectrometer can be used to select and record the response from target compounds at high resolution and with a high sensitivity. The high resolution enables chemical background masses to be eliminated and consequently allows a lower detection level to be achieved. Selected ion recording provides a much better duty cycle, and therefore sensitivity, than scanning.

The detection and quantification of polychlorinated dibenzo-*p*-dioxins, and in particular the 2,3,7,8-tetrachlorinated dibenzo-*p*-dioxin (2,3,7,8-TCDD), is a major application for double-focusing magnetic sector mass

Figure 6 Detection of 5 femtogram of 2,3,7,8-TCDD with S/N greater than 10:1 from an injection of 1 μ L onto a GC capillary column and 'selective ion recording' of four masses plus a 'lock mass' at 10000 resolving power (10% valley definition).

spectrometers. Despite extensive clean-up procedures, samples still contain compounds such as polychlorinated biphenyls and benzyl phenyl ethers, which have the same nominal masses as the compounds of interest. The sample is 'spiked' with a known amount of the ^{13}C isotope labelled form of 2,3,7,8-TCDD, introduced via gas chromatography and recorded by 'high-resolution' mass spectrometry. The measurement is quantified by comparison of the native dioxin response to that from the ^{13}C -labelled form, and verified by confirmation of the ratio of the major isotopes of both the native and the ^{13}C -labelled dioxins. At 10000 resolving power (10% valley definition) the detection level for 2,3,7,8-TCDD is about 1 femtogram, or 3 attomole (Figure 6).

Metastable Ion Analysis and MS/MS

The decomposition of a precursor or 'parent' molecular ion to a product or 'daughter' ion, while in flight through a single focusing magnetic sector mass spectrometer, can give rise to an artefact peak in the mass spectrum. However, such artefact peaks can be instructive in understanding the structure of the precursor ion. Methods have been developed for double-focusing instruments to eliminate such artefact peaks from mass spectra, to specifically record daughter ions from a selected

parent ion, and to detect specific parent–daughter ion transitions as a means of detecting target compounds or classes of compounds.

If a parent ion (mass m_p) fragments in a field-free region, the daughter ion (mass m_d) retains the velocity of the parent, only modified by the addition of a velocity component as a result of energy released in the decomposition reaction. Hence, the ratio of the daughter ion kinetic energy to that of the parent is equal to the ratio of their masses (m_d/m_p). The additional velocity component is randomly distributed and this is seen as a superimposed energy spread.

Single-Focusing Magnetic Sector

If a parent ion fragments in the flight path between the source and the magnetic field, or the 'first field-free region', the daughter ion has an energy relative to that of the parent in proportion to the ratio of their masses (m_d/m_p). Ions originating in the ion source are accelerated to the same kinetic energy. Consequently, after traversing the magnetic sector, the daughter ion appears at a different mass (m^*) when viewed relative to the normal spectrum. The apparent mass is given by:

$$m^* = m_d \cdot (m_d/m_p) \quad [10]$$

The daughter ion peak is often recognizable since it is usually broader as a result of its increased energy spread. The parent and daughter ions can often be deduced from m^* with reasonable confidence if the sample is pure, but not if a mixture. This can provide useful additional information or become a source of noise depending on the circumstances.

Double-Focusing Magnetic Sector

If a parent ion fragments in the 'first field-free region' of a double-focusing mass spectrometer, the daughter ion, which will have a lower kinetic energy, is unlikely to be transmitted by the electric sector and therefore will not appear in the mass spectrum. If a parent ion fragments in the field-free region preceding the final sector, the situation is more complex. The daughter ion can be transmitted through the final (magnetic) sector of a 'forward geometry' arrangement just as it would be in a single-focusing sector design, but will not be transmitted through the final (electric) sector of a 'reverse geometry' or 'split geometry' arrangement. In these latter cases, if the final electric sector only is scanned, the daughter ion will be transmitted when the electric field is at value equal to (m_d/m_p) of the value required to transmit 'full energy' ions originating from the source. The result is a spectrum of all the daughter ions of the parent ion transmitted by the magnetic sector. The electric sector scan is a spectrum of ion energies, and therefore will also

Table 1 Linked magnetic field (B) and electric field (E) scans for the study of metastable ion decompositions on double-focusing magnetic sector mass spectrometers

Type of analysis	'Field-free region' in which decomposition takes place	
	First	Penultimate (Final sector is electric)
Daughter ions ($m_d = \text{constant}$)	$B/E = \text{constant}$	$B = \text{constant}$ (E scan only)
Parent ions ($m_p = \text{constant}$)	$B^2/E = \text{constant}$	$B^2E = \text{constant}$
Constant neutral loss ($m_p - m_d = \text{constant}$)	$(B/E)^2(1 - E') = \text{constant}$	$B^2(1 - E') = \text{constant}$

$E' = E/E_o$, where E_o is the electric field for transmission of undissociated parent ions.

exhibit the energy distribution of daughter ions, albeit at the cost of low 'mass' resolution. This is known as a 'mass analysed ion kinetic energy spectrum' (MIKES).

Transitions occurring in the 'first field-free region' of a double-focusing mass spectrometer can be studied by scanning the electric sector (E) and magnetic sector (B) fields synchronously such that the ratio B/E is constant, determined by the value of the selected precursor ion mass (m_p). This is known as ' B/E linked scanning'. The dissociation energy information is lost as a result of the double-focusing action of the combined electric and magnetic sectors but on the other hand the observed daughter ion 'mass' resolution is increased.

Different types of linked magnetic sector field (B) and electric sector field (E) scans can yield different information from transitions in the first field-free region, and from the penultimate field-free region where the final sector is an electric sector. These include 'parent ion scans' in which spectra of all the parent ions from which a selected daughter ion (m_d) are obtained, and 'constant neutral loss scans' in which spectra of all the transitions in which the same neutral loss ($m_p - m_d$) occur. These are listed in **Table 1**.

Sector mass spectrometers with two or more sectors, and gas 'cells' in which 'high energy' ion–molecule collisions take place, are used to study ion and neutral chemistry. Tandem sector mass spectrometers with up to six sectors (two magnetic and four electric sectors in EBEEBE sequence) have been constructed to study

ion–molecule interactions, multistep dissociations and neutralization–reionization processes.

I_p	count rate of product ion
k	rate coefficient
k_f	forward rate coefficient
k_r	reverse rate coefficient
n_M	concentration of trace gas M
n_1	number density of reactant charged particles
n_2	number density of buffer gas
n_3	number density of reactant neutral particles
T_g	buffer gas temperature
t	reaction time
u	ion mass-to-charge ratio
ν	frequency

creation of an ensemble of reactant charged particles of number density n_1 in an inert buffer gas of number density n_2 such that $n_1 \ll n_2$. Then multiple collisions between the charged particles and the buffer gas ensure the randomization (Maxwellianization) of the charged particle velocities and the relaxation of the charged particle mean energies (which may be high initially) to those appropriate to the buffer gas temperature, T_g . Then the introduction of reactant neutral atoms or molecules at a number density, n_3 , ($n_3 \ll n_2$) initiates an ion neutral reaction. Thus the rate of change of n_1 as a function of n_3 can be determined, and the rate of coefficient, k , for the reaction can be calculated since:

$$\begin{aligned}\frac{dn_1}{dt} &= -kn_1n_3 \Rightarrow n_1(t) = n_1(0)\exp(-kn_3t) \\ &\Rightarrow \ln n_1(t) = \ln n_1(0) - kn_3t\end{aligned}\quad [1]$$

Introduction

The selected ion flow tube, SIFT, technique is a fast-flow tube/ion-swarm method for the study of the reactions of ions (positive or negative) with atoms and molecules under truly thermalized conditions over a wide range of temperature. It has been extensively used to study ion–molecule kinetics. Its application to atmospheric and interstellar ion chemistry by several eminent groups over a 20-year period has been crucial to the advancement and understanding of these interesting topics. More recently it has been developed as a very sensitive analytical technique for the detection and quantification of trace gases in air and in human breath down to the ppb level and in real time.

Principle of the SIFT

The SIFT technique was developed because the original fast-flow-tube method, the eminently productive flowing afterglow technique, was not suitable for the study of the reactions considered at that time to be involved in the complex ion chemistry of interstellar clouds. The SIFT (and the flowing afterglow) are flow-tube ‘swarm’ experiments. The ‘ideal’ swarm experiment involves the

The k and the ion products of the reaction (determined at the defined temperature T_g) are the important parameters needed to model the ion chemistry of ionized media. In a flow system the reaction time t is the length of the reaction zone divided by the ion-flow velocity.

In the SIFT apparatus the ions are created in an ion source which is external to the flow tube. The ions are then extracted from the ion source, selected according to their mass-to-charge ratio using a quadrupole mass filter (see **Figure 1**) and injected into a flowing carrier gas (usually helium at a pressure of 0.5 Torr) via a small orifice (typically ~ 1 mm diameter). The carrier gas is inhibited from entering the quadrupole mass filter chamber by injecting it into the flow tube through a Venturi-type inlet at near-supersonic velocity in a direction away from the orifice (see **Figure 1**). In this way a swarm of a single-ion species thermalized at the same temperature as the carrier gas are convected along the flow tube (which is usually ~ 1 m long), sampled by a downstream pinhole orifice, mass analysed and counted by a differentially pumped quadrupole mass spectrometer system.

To study a particular ion–molecule reaction, a reactant gas is introduced at a measured flow rate into the carrier gas. Then by measuring the count rates, I , of the reactant and product ions using the downstream mass spectrometer and relating them to the number density of

Figure 1 Schematic representation of a SIFT apparatus. One form of Venturi-type inlet is shown in the upper-left part of the diagram. The vacuum jacket facilitates operation at high and low temperatures.

Figure 2 Dependence of the ion count rate on the H_2 number density for the reaction of CH^+ with H_2 . The rate coefficient, k , is obtained from the slope of the linear decay plot following eqn [1]. The primary product ion is CH_2^+ . The CH_3^+ ion is produced in the secondary reaction of CH_2^+ with H_2 .

the reactant gas in the carrier gas, the k for the reaction (following eqn [1]) and the ion products can readily be determined (see **Figure 2**). Some SIFT apparatuses can be operated over the wide temperature range 80–600 K. Constructional details for a SIFT are given in some of the cited reviews.

No electrons are present in the carrier gas and therefore the SIFT medium is not a gaseous plasma medium like the flowing afterglow but rather a swarm of

positive or negative ions in the carrier gas. Notwithstanding the great success of the flowing afterglow for the study of ion–neutral reactions, it has a serious limitation in that the primary reactant ions may react with their parent (source) gas which is usually present in the carrier gas, and this complicates the interpretation of the mass spectrometric data. This is avoided in the SIFT by the upstream external ion source/mass filter system. So, for example, if methane is introduced into the SIFT ion source, C^+ , CH^+ , CH_2^+ , CH_3^+ or CH_4^+ (and even CH_5^+) can be separately injected into the flowing carrier gas. Significantly, the CH_4 source gas is not present in the helium carrier gas and cannot therefore confuse kinetics studies.

The rate coefficients and ion products of the reactions with many gases of practically any positive or negative ion species can be studied using the SIFT, provided that the ions can be extracted from the ion source at a sufficient current ($\sim 10^{-9}$ A is the practical lower limit) and can be injected at a sufficiently low energy to avoid their fragmentation in collisions with the carrier gas. Even weakly bound species such as $\text{H}_3\text{O}^+(\text{H}_2\text{O})_3$ ions have been injected without undue dissociation. Low-pressure and high-pressure electron-impact sources and even flowing afterglow sources are routinely used to prepare a wide variety of positive and negative ions. For our recent development of the SIFT for trace gas analysis, a microwave discharge source is used (see below).

A fraction of the ions produced in SIFT ion sources may be electronically and vibrationally excited and after

Figure 3 A typical SIFT decay (c/s = counts per second) obtained when two differently reacting species are present at the same mass. In this example, the excited ion $\text{Xe}^+ (^2\text{P}_{1/2})$ reacts more slowly with Cl_2 than the ground state $\text{Xe}^+ (^2\text{P}_{3/2})$ ion.

injection survive in the inert carrier gas. Their reactions can then be studied and if their reactivity is different from their ground state analogues, the decay curves from which the rate coefficients are derived are nonlinear (see **Figure 3**). However, excited ions can often be relaxed to their ground states by the addition of a suitable 'quenching' gas.

Using SIFT apparatuses, the rate coefficients and products ions for a large number of positive ion–neutral and negative ion–neutral reactions have been studied in several laboratories around the world. They include the bimolecular reactions of doubly charged ions, electronically and vibrationally excited ions and cluster ions, and termolecular association reactions, some over a wide range of temperature. This has led to a greater understanding of the mechanisms, kinetics and energetics of such reactions and also to a clearer understanding of the ion chemistry of ionized media.

Ion Chemistry of the Terrestrial Atmosphere and Interstellar Clouds

The SIFT is ideally suited to the study of the ion chemistries of the terrestrial atmosphere, TA, and interstellar clouds, ISC. These are ionized media in which gas phase ion–neutral reactions occur which produce the exotic ions and molecules observed in these regions. The challenge to ion chemists is to identify these reactions, and to this end the SIFT has made a major contribution.

Atmospheric Ion Chemistry

In the tenuous upper TA (above 100 km altitude; the ionospheric E- and F-regions) the ion chemistry is simple. Only bimolecular reactions occur between the precursor ions H^+ , He^+ , O^+ , N^+ , O_2^+ and N_2^+ (formed by photoionization) and the ambient neutrals O, O_2 and N_2 , e.g.

The k and the product ion distributions for such reactions are readily determined using the SIFT. Rocket-borne mass spectrometers have shown that NO^+ ions are a major species in the upper TA, even though neutral NO does not exist in measurable concentrations. Flowing afterglow and SIFT experiments have shown that these ions result primarily from the ion–molecule reaction:

The ion chemistry of the upper TA (summarized in **Figure 4**) proceeds to convert the energetic precursor ions to the less energetic, predominantly diatomic molecular ions, which can be neutralized by the ambient free electrons via the process of dissociative recombination as shown. It was also realized that metastable electronically excited ions of O^+ and O_2^+ are produced in the upper ionosphere and so it became important to study the reactions of these excited ions. The SIFT is well suited to these studies (excited ions are quenched in flowing afterglow plasmas). The chemistry of these excited species is represented in **Figure 4** by the thick lines.

The ion chemistry of the lower TA (below 100 km) is dominated by termolecular (three-body) reactions of both positive ions and negative ions. At altitudes between about 50 and 90 km, in the ionospheric D-region, most ionizing solar radiations have been filtered out except for L_α and L_β radiation, which can selectively ionize NO and $\text{O}_2(^1\Delta_g)$ molecules. So the initial ions in the positive ion chemistry are NO^+ and O_2^+ .

SIFT and flowing afterglow studies have shown that both NO^+ and O_2^+ are relatively unreactive in bimolecular collisions with the major ambient atmospheric neutrals, but they both undergo termolecular (three-body) reactions forming weakly bonded association ions, an important initial reactions in the D-region being:

These weakly bonded $\text{NO}^+ \cdot \text{N}_2$ ions react efficiently with the ambient CO_2 and H_2O molecules in the

Figure 4 The ion chemistry of the upper terrestrial atmosphere. Only biomolecular ion–neutral reactions occur, and ion–electron reactions (dissociative recombination) maintain the ionization equilibrium.

‘switching reactions’:

Termolecular H_2O addition reactions build up the NO^+ hydrates $\text{NO}^+(\text{H}_2\text{O})_{2,3}$. Finally the NO^+ is ‘switched out’ from the latter ions thus:

Further termolecular reactions produce the hydrated hydronium ions $\text{H}_3\text{O}^+(\text{H}_2\text{O})_m$ which are observed to be the major positive ions in this altitude region.

In the lowest altitude region of the TA the initial positive ions, e.g. O_2^+ and N_2^+ , formed by cosmic ray ionization, are quickly converted to the dimer ions O_4^+ and N_4^+ , which undergo switching reactions with the relatively abundant H_2O and CO_2 to finally produce $\text{H}_3\text{O}^+(\text{H}_2\text{O})_m$ (see the left part of **Figure 5**). The chemistry does not stop here, because the many minor reactive species that exist in the lowest part of TA, such as the bases NH_3 , CH_3CN and CH_3OH , undergo ligand

switching with the hydrated hydronium ions producing ‘mixed’ cluster ions, e.g.

Switching reactions like [7] can be studied in the SIFT because of the facility to inject cluster ions without undue break-up.

The negative ion chemistry in the lower TA (see the right part of **Figure 5**) is initiated by the electron attachment reactions:

This chemistry follows a similar pattern to the positive ion chemistry in that the initial ions O^- and O_2^- are converted to O_3^- and O_4^- and these undergo switching reactions with H_2O and CO_2 to produce ions such as $\text{O}_2^- \cdot \text{H}_2\text{O}$, $\text{O}_2^- \cdot \text{CO}_2$ and CO_3^- . The further reactions of these ions with other minor neutral species such as NO_x molecules result in the very stable negative ion NO_3^- . This ion undergoes termolecular association reactions with H_2O producing $\text{NO}_3^- \cdot (\text{H}_2\text{O})_n$ cluster ions which dominate the ionospheric D-region. At even lower altitudes the production of NO_3^- and its hydrates is followed by their reactions with acids, mostly HNO_3 and H_2SO_4 (produced from pollutant NO_x and SO_2 in the parallel neutral chemistry that is occurring in the lower TA). These reactions produce cluster ions like $\text{NO}_3^-(\text{HNO}_3)_{2,3}$ and $\text{HSO}_4^-(\text{HNO}_3)_n$. However, the large ambient concentration of H_2O shifts the equilibrium to the right in the generalized reaction:

producing the mixed cluster ions indicated. The SIFT has been of great value in the study of these and many other reactions of cluster ions.

Interstellar Ion Chemistry

One of the most interesting events in astronomy during the last few decades has been the discovery of many types of molecules, both ionized and neutral, in the diffuse and dense ISC that pervade the Milky Way galaxy. These ISC are at such enormous distances from the solar system that *in situ* probes, e.g. conventional mass spectrometers, cannot be exploited to analyse their composition. The only tool available to probe their physical conditions and chemical compositions is spectroscopy over the whole spectral range (from radio waves to gamma rays). The diffuse clouds of very low number density (about 10^2 cm^{-3}) consist mainly of H and H_2 together with C, N and O atoms which play a central role in the gas phase ion chemistry. The dense clouds of much higher number

Figure 5 The ion chemistry of the lower atmosphere. The positive ion chemistry (left column) and the negative ion chemistry (right column) are dominated by termolecular reactions, finally producing the cluster ions in the lower boxes.

Figure 6 The initial steps in the ion chemistry of interstellar clouds leading to H_2O , NH_3 and CH_4 (see also Figure 7).

Figure 7 The production of polyatomic ions and neutral molecules in dense ISC following the radiative association reactions (thick arrows) of CH_3^+ with several known interstellar molecules and the subsequent dissociative recombination.

Figure 8 A SIFT apparatus configured for trace gas analysis, with the stable discharge ion-source for H_3O^+ , NO^+ and O_2^+ ions, and a single air/breath sample inlet port.

Figure 9 Concentration time profiles of the trace gases acetone and isoprene in single exhalations of breath obtained with the SIFT using H_3O^+ , NO^+ and O_2^+ precursor ions. Concentrations are given in parts per million (ppm) of the breath.

density (10^4 – 10^3 cm^{-3}) consist mainly of H_2 and He together with minority C, N and O atoms.

In diffuse ISC it is stellar ultraviolet and galactic cosmic rays that largely create the ions, the important initial ions being C^+ , H^+ , H_2^+ and He^{*+} . The dense ISC through which ultraviolet cannot penetrate because of the presence of micrometre-sized ‘dust’ grains are ionized by galactic cosmic rays producing H^+ , and H_2^+ and He^{*+} . From these initial positive ions begin the gas phase ion chemistries illustrated in **Figures 6** and **7**. The SIFT is especially valuable for the study of interstellar ion chemistry and (together with the ion cyclotron resonance technique) has provided the major contribution to this field.

The primary H^+ ions can react with O atoms by ‘accidental resonance’ charge transfer producing O^{*+} ions, which react rapidly with H_2 producing OH^+ . The H_2^{*+} primary ions react rapidly with H_2 producing H_3^+ , which transfers a proton to O atoms also producing OH^+

The OH^+ ions react with H_2 to give H_2O^{*+} , which then reacts with H_2 to give H_3O^+ in the sequence of H-atom abstraction reactions indicated in **Figure 6**. The closed-shell ion H_3O^+ ends this chain, since it does not react with H_2 , but it does undergo dissociative recombination with electrons, producing OH and H_2O molecules. A similar sequence of H-atom abstraction reactions probably leads to the production of NH, NH_2 and NH_3 in ISC as is indicated in **Figure 6**. This sequence begins with N^+ ions produced from He^{*+} (via eqn [2]). The reaction of H_3^+ with N atoms is also involved in NH_3 production. Similar sequences lead to small hydrocarbon molecules. These sequences of reactions can readily be studied using the selected ion injection facility of the SIFT.

The ion chemistry that results in the polyatomic hydrocarbon molecules observed in dense ISC can begin with slow radiative association reaction (see below) of C^+ with H_2 , producing CH_2^+ ions which then react rapidly with H_2 to form CH_3^+ . The last ion can also be produced by the sequence of reactions beginning with the proton transfer reaction of H_3^+ with C atoms producing CH^+ ions, whence:

SIFT studies have shown that these bimolecular reactions are very fast, but that CH_3^+ reacts only slowly with H_2 in a termolecular association reaction producing CH_5^+ thus:

Such termolecular reactions proceed via the formation of a loosely bound excited ion, e.g.

which can be stabilized against decomposition at sufficiently high pressures in collisions with an inert third body M, leaving M internally or kinetically excited thus:

The kinetics of such termolecular reactions are well understood, and many have been studied using the SIFT. However, they cannot occur in ISC because the pressures

Figure 10 A mass spectrum obtained using H_3O^+ , precursor ions following the introduction of laboratory air into the SIFT. Concentrations of the detected species (released from an adjacent laboratory) are given in parts per billion (ppb) in parentheses. u = ion mass-to-charge ratio, c/s = counts per second.

in these regions are very low. Instead, the analogous process of radiative association occurs. Continuing with the above example, the bimolecular reactions [13] can occur in ISC, and indeed it is promoted by the low ambient temperatures (as low as 10 K in some clouds), and if the dissociation lifetime of the excited $(\text{CH}_5^+)^*$ ion is long enough, then it may emit a photon which will stabilize it against dissociation:

Radiative association reactions are very important in ISC chemistry and lead to the production of many of the observed polyatomic molecules in these regions. The CH_5^+ ions formed in reaction [15] are neutralized by electrons in ISC to form CH_4 (see **Figure 7**).

SIFT studies have shown that CH_3^+ ions readily undergo termolecular association reactions with many known interstellar molecular species, including CO, H_2O , HCN, NH_3 , CH_3OH and CH_3CN . These ion-molecule associations must surely proceed via radiative association in dense ISC, and in this way complex molecules can be formed, as is indicated in **Figure 7**. Thus these SIFT studies have been crucial in indicating the importance of radiative association reactions in ISC.

Many of the molecular species detected in dense interstellar clouds are seen to contain the rare (heavy) isotopes of some elements (e.g. D, ^{13}C , ^{18}O , etc.). However, at first sight the abundance ratios of some molecules containing the rare and common isotopes (e.g. DCN/HCN) were very surprising because they are orders-of-

magnitude greater than those expected from their cosmic isotopic ratios. Following extensive SIFT studies, it is now understood that this is due to the phenomenon of 'isotope fractionation' in gas phase ion-molecule reactions. This phenomenon is exemplified by the elementary reaction:

It is a simple matter to determine the forward (exothermic) and reverse (endothermic) rate coefficients, k_f and k_r for such reactions using the SIFT technique (ideally suited for such studies because separate isotopic ions can be injected and the reaction temperature can be accurately controlled even down to 80 K). For reactions [16] it is observed that k_f increasingly exceeds k_r as the temperature is reduced. This is because the reverse reaction is endothermic by 39.8 meV (3.84 kJ mol^{-1}), by virtue of the zero-point-energy difference between H_2 and HD, and the ionization energies of H and D differ by 4 meV (0.38 kJ mol^{-1}). Hence in cold ISC the reverse reaction is effectively stopped whilst the forward reaction proceeds at the gas kinetic rate. This effectively ensures that much of the deuterium in dense interstellar clouds is contained in HD. Also important in ISC are the reactions:

in which D is fractionated into H_2D^+ and CH_2D^+ . Thus the subsequent reactions of these deuterated ions

Figure 11 The SIFT analyses of an air–acetone mixture using H_3O^+ , NO^+ and O_2^+ precursor ions injected sequentially into the carrier gas by switching the upstream mass filter (see **Figure 8**).

(occurring, of course, in parallel with the H_3^+ and CH_3^+ reactions) result in the enrichment of deuterium in many interstellar molecules. Similarly, SIFT studies have shown that fractionation of the rare isotopes of heavier elements also occurs, notably of ^{13}C into the very abundant interstellar molecule CO via the reaction of $^{13}\text{C}^+$ with ^{12}CO .

Trace Gas Analysis; SIFT/MS

The SIFT can be used for accurate determinations of the concentrations n_{M} of trace gases, M, in an air sample that has been introduced into the carrier gas, if the rate

coefficients k are known for the reactions of a chosen injected precursor ion species with the M. Measurements of the count rates at the downstream mass spectrometer system of the precursor ion and each product ion, I_1 and I_{p} respectively, provide values of n_{M} for each trace gas if $I_{\text{p}} \ll I_1$. Then following eqn [1]:

$$n_{\text{M}} = \frac{I_{\text{p}}}{I_1 k t} \quad [18]$$

Since currently I_1 may be typically 10^5 precursor ions per second, a typical k is $10^{-9} \text{ cm}^3 \text{ s}^{-1}$ and the reaction time t is of the order 10^{-2} s . Then for I_{p} at the low value of one product ion per second (a sensible detection limit),

Figure 12 Mass spectra obtained in the SIFT for an air–gasoline vapour mixture using H_3O^+ and O_2^+ precursor ions. The component hydrocarbon molecules M , are protonated by H_3O^+ producing MH^+ ions, whereas charge transfer between O_2^+ and the M produces ions like M^+ and $(\text{M}-\text{H})^+$. u = ion mass-to-charge ratio, c/s = counts per second.

n_{M} in the carrier gas is 10^6 cm^{-3} . This is a fractional number density of 10^{-10} of that of the helium carrier atoms (usually 10^{16} cm^{-3}). Thus for an air or breath sample introduced into the carrier gas at a relative concentration of 1% of the carrier gas, trace gases at a partial pressure of 10 parts per billion (ppb) can be detected and quantified. Clearly, for large I_1 , greater air sample concentrations, and longer integration times for I_p , the sensitivity can be improved and the detection limit lowered. The experimental configuration for this SIFT analytical method is indicated in **Figure 8**. A transportable version of the SIFT is now available commercially for use *in situ* for breath and environmental analyses.

This analytical method can be easily used for the detection and accurate quantification of several trace gases simultaneously in multicomponent vapour mixtures such as polluted air and human breath. This can be achieved in real time because of the short time response of the method ($t \sim 10^{-2} \text{ s}$), by rapidly switching the downstream mass spectrometer between chosen precursor and product ion masses. Thus the time profiles of the concentration of several trace gases in breath can be obtained from single exhalations, as are shown in **Figure 9**. Samples introduced into the apparatus directly from the atmosphere or from containers can be analysed by multiscanning the downstream mass spectrometer. A

Figure 13 The mean concentrations of acetone and ammonia (ppb) obtained by the SIFT in single exhalations of breath from six volunteers following a protein meal taken at time 0 (see the text). The vertical bars represent the standard deviations of the six concentrations at each time.

Figure 14 The SIFT spectrum obtained following the introduction of breath from a diabetic patient with end-stage renal failure who smokes cigarettes (see the text). The concentrations of the major breath gases are given in ppb in parentheses. u = mass, c/s = counts per second.

spectrum obtained by sampling the SIFT laboratory air is shown in **Figure 10**.

A vital point to note is that the mass spectrum of the product ions is much simpler than would be obtained using electron impact ionization of the air or breath sample, because chemical ionization is used. However, only a limited number of precursor ions can be used, which must not react at a significant rate with the major components of air or breath, N₂, O₂, CO₂, H₂O and Ar, but obviously must react efficiently with the trace gases in the sample. In this respect H₃O⁺, NO⁺ and O₂⁺ are the prime candidates, and SIFT studies of a great number of the reactions of these three ions with a wide variety of organic and inorganic compounds have shown that H₃O⁺ and NO⁺ are of widest application, with O₂⁺ being useful for fewer particular trace gases.

Recent SIFT studies have shown that H₃O⁺ transfers a proton at the gas kinetic (maximum efficiency) rate to all molecules, M, that have proton affinities greater than H₂O molecules, and usually only a single product ion MH⁺ is formed, which greatly simplifies the analysis of the product ion mass spectrum. However, two products are sometimes observed from these proton transfer reactions, as is the case for some aldehyde reactions, e.g.

NO⁺ ions often react with organic molecules via hydride ion (H[−]) transfer producing (M−H)⁺ ions and HNO molecules, e.g.

They react with most carboxylic acids and with tertiary alcohols via hydroxide ion (OH[−]) transfer producing (M−OH)⁺ ions and HNO₂ molecules, and undergo rapid association reactions with most ketones producing NO⁺•M ions.

O₂⁺ is particularly useful as a precursor ion for species of low proton affinity that do not react with H₃O⁺ and of high ionization potential that do not react with NO⁺. The reaction process is invariably charge transfer; it is particularly useful for quantifying NO, NO₂ and NH₃ in air:

The beauty of this SIFT/MS analytical technique is that all three suitable precursor ion species can be used on the same air or breath sample by switching the upstream mass filter (see **Figure 8**). **Figure 11** shows the results obtained simply for an air–acetone sample. The

use of two or three precursor ions ensures that few of the various trace gases in the sample are missed.

An extensive database is required of the rate coefficients and product ions of the reactions of H₃O⁺, NO⁺ and O₂⁺ with many different types of molecules, and this has been compiled from SIFT experiments. With sufficient knowledge of the ion chemistry, very complex mass spectra can be analysed, such as those shown in **Figure 12**, obtained for a sample of the volatiles from gasoline using both H₃O⁺ and O₂⁺ precursor ions. Note the identification of the aromatic and aliphatic hydrocarbons, each compound of mass *M*, being recognized as MH⁺ ions in the H₃O⁺ spectrum (proton transfer) and M⁺ ions in the O₂⁺ spectrum (charge transfer).

The potential of this SIFT/MS analytical method is enormous for human breath analysis and hence in physiology and biochemistry, for clinical diagnosis and therapeutic monitoring, and for measuring air pollution and analysing food vapour emissions and food flavours. The medical and biochemical value is well illustrated by the analyses of the breath of six healthy individuals following the morning ingestion of a liquid protein meal. The breath concentrations of five species (ammonia, methanol, ethanol, acetone and isoprene) were obtained from only single breath exhalations before and some six hours after the meal. Shown in **Figure 13** are the rise in the ammonia levels as the protein is metabolized and the decrease in the acetone as the body is nourished.

SIFT/MS analyses of the breath of some 30 uraemic patients with end-stage renal failure have shown greatly elevated levels of ammonia compared to healthy subjects. The spectrum obtained of breath of a uraemic patient with diabetes (indicated by the elevated acetone level) who also smokes cigarettes (indicated by the presence of acetonitrile) is shown in **Figure 14**. Many further applications of this new method for trace gas analysis are in train including applications in agriculture (animal welfare) and grassland research.

Principles of Nuclear Medicine Imaging

The general term nuclear medicine (NM) encompasses a number of different techniques that all use unsealed radioactive compounds for diagnosis or therapy. NM imaging belongs to the first application. Its objective is to measure and visualize the distribution of a radiotracer that has been introduced into a human body. The basic principle is simple: a disease-specific pharmaceutical, molecules of which have been labeled with radioactive isotope, is administered to a patient, usually by intravenous injection. The molecules are designed to go to and localize in an organ or area of interest. This tracer's radioactive emissions, measured outside the body, are used to create two- or three-dimensional (2D or 3D) images that, viewed by an NM physician, provide him/her with information about the organ's function, normal or altered by disease, its physiology, and metabolism.

There are two types of NM imaging. Ultimately both of them, although based on different principles, use detection of gamma rays to create diagnostic images. Positron emission tomography (PET) uses isotopes decaying by positron emission (β^+ decay). An emitted positron almost immediately annihilates with an electron in the medium. Coincident detection of two collinear 511 keV photons created in this annihilation is used to produce 3D images of the radiotracer distribution in the body.

Single-photon emission imaging (also called scintigraphic imaging) uses isotopes that decay with photon emission. Since these photons are recorded individually, as opposed to measuring coincident pairs of photons in PET, the modality is referred to as single-photon imaging. The emitted photons are measured outside the patient body by a gamma camera (also called an Anger or scintillation camera), which may have one, two, or even three detectors (camera heads). Depending on the diagnostic question, the scan is performed following one of many clinical protocols. In the simplest acquisition, data are collected in planar mode where the camera remains stationary for the whole duration of the scan. Alternatively, it can move slowly along the length of the patient acquiring a whole-body image. In both of these cases, the resulting image represents a 2D projection of the 3D distribution of radiotracer in the body. When the camera rotates and multiple projections are acquired at different locations around the patient, a 3D radiotracer representation may be obtained using one of the tomographic reconstruction methods. This technique is referred to as single-photon emission computed tomography (SPECT), and the camera that is able to acquire and process tomographic studies is called a SPECT system. Otherwise, dynamic studies can be performed where a series of 2D planar images is acquired over time, allowing physicians to visualize temporal changes in the tracer distribution, thus providing diagnostic information about body functions. Finally, dynamic 3D images of a beating heart may be acquired by correlating data acquisition with the electric signal from the heart (EKG).

Figure 1 shows three examples of modern clinical SPECT systems. The Philips SKYlight system presented in **Figure 1(a)** does not have a traditional gantry; instead its two detectors (camera heads) move relatively freely on special arms. This design allows for high flexibility in scanning patients of almost any size and in any position. **Figure 1(b)** and **1(c)** shows the General Electric (GE) Infinia Hawkeye and Siemens Symbia SPECT/CT systems, respectively. Both SPECT cameras have two detectors rotating in open gantry configurations. The detectors can be positioned at 90° to each other for cardiac scans or, alternatively, at 180° configuration, parallel to each other, for a number of other imaging applications. Both cameras are additionally equipped with CT imaging systems.

Imaging Equipment

Anger Camera

The most important element of an Anger camera is the detector, which in the majority of systems currently used is an NaI(Tl) (sodium iodine doped with thallium) scintillation crystal. Each head in a modern SPECT camera contains one large rectangular detector with an active surface of approximately 50×40 cm and a thickness of 0.9 cm. Behind the crystal is an array of 50–90 photomultiplier tubes (PMTs), the associated electronics, and analog-to-digital converters. The role of the PMT is to measure the energy of each detected photon and the exact location of its interaction with the crystal material. Currently used cameras are optimized for photons in the 70–400 keV energy range and have relative energy resolution of approximately 9%. Their intrinsic spatial resolution is of the order of 3–3.5 mm.

The NaI(Tl) crystals are highly efficient at converting gamma photons into visible light photons. Additionally, since the amount of light is proportional to the energy of incident photons, it is possible to discriminate detected events based on their energy. However, relatively poor energy resolution makes elimination of scattered photons, which arrive at the camera with energy lower than the original ones, difficult. A number of other detector materials have also been investigated for potential use in a gamma camera. Although semiconductor crystals, such as Ge(Li) or high-purity germanium, provide substantially better energy resolution than NaI, they have low detection efficiency, high cost, and complicated maintenance (liquid nitrogen cooling). For a number of years, the use of cadmium zinc telluride (CdZnTe or CZT) has been considered, but only very recently have prototype SPECT imaging systems based on CZT crystals become available. This very promising solid state detector has much better energy resolution than NaI(Tl) (approximately 5–6%), works at room temperature, and does not require photomultipliers to read the signal. Another attractive characteristic of the CZT detector is its excellent intrinsic spatial resolution, presently

reaching 0.5 mm, however, requiring thousands of individual electronic channels. Additionally, although new SPECT cameras with CZT detectors are very promising, the material is still rather costly and its production difficult. Only small crystals can be grown (approximately $2 \times 2 \times 0.5$ cm), and often there are problems with the consistency of their spectral performances. Therefore, CZT cameras use pixilated arrays of detectors and are currently available only in small field-of-view (FOV) configurations for small animal and cardiac applications.

Another vital component of each Anger camera is its collimator. **Figure 2** presents a schematic drawing of a typical camera configuration showing all its main components: the collimator, the detector, phototubes, associated electronics, and computer. The role of the collimator, which is placed in front of the detector, is to determine the direction of incident photons. This is achieved by restricting the angular distribution of photons that may reach the detector surface. The collimator consists of a sheet of a highly attenuating material (usually lead) with many thousands of small hexagonal holes. Only photons that arrive within the acceptance angle of the collimator can reach the detector surface. There is a small probability that some photons with incident angle greater than the acceptance angle will pass through the collimator walls (septa) and be detected; this effect is called septal penetration.

Most clinical applications use parallel-hole collimators with holes perpendicular to the surface of the crystal. Theoretically, such collimators accept only photons traveling normal to the detector; thus, there is a direct relationship between the spatial distribution of the radiopharmaceutical and the resulting image. Obviously, the real collimator accepts not only photons parallel to the septa but also all those that arrive within a small cone corresponding to the acceptance angle, and as a result the area seen by each hole increases with distance. This means that the resolution of the camera is distance dependent and deteriorates as the distance between the source and the collimator increases. This effect is called collimator blurring and can be partly compensated for

Figure 2 Diagram of a typical Anger camera with all its main components.

when iterative image reconstruction is used. It is generally recognized that the typical resolution of SPECT is of the order of 1–2 cm. This value results from combined resolution of the collimator measured at a clinically relevant distance and the intrinsic resolution of a detector.

As the majority of photons that are emitted by a patient body are absorbed in the collimator septa, the typical parallel-hole SPECT collimator has low sensitivity, accepting approximately only one photon for every 10^4 emitted. Collimators with larger holes provide higher photon detection efficiency, but increase the acceptance angle and thereby lower the detector spatial resolution. In practice, each clinical camera has two or three sets of exchangeable collimators with different hole sizes and septal thicknesses. The collimator selected depends on the type of study; for example, different collimators are used in scans involving radiotracers emitting low- or high-energy photons, requiring high resolution or high sensitivity.

Other collimator types, such as pinhole, cone beam, and fan beam, produce magnified images of an object and therefore may be used for imaging of small organs (e.g., the thyroid, wrist, or brain). Although cone-beam and fan-beam collimators usually have slightly higher sensitivity than parallel-hole collimators, typically the sensitivity of a pinhole collimator is very low. All of these collimators, when used in tomographic (SPECT) imaging, require special algorithms for image reconstruction, which take into account the geometry of data acquisition.

To improve detection sensitivity, collimators with multiple pinholes have been designed. They offer excellent resolution, while maintaining acceptable sensitivity. For this reason, they have become very popular in preclinical (small animal) SPECT systems, where nonoverlapping or overlapping hole configurations are

used. These systems have much better resolution (0.5–2 mm) and sensitivity ($\sim 0.3\%$) than clinical SPECT cameras (10–20 mm and 0.01–0.03%, respectively). These characteristics, however, apply only to a very small FOV (5–8 cm).

The light created by photon interactions in the crystal is amplified and converted to an electrical signal by an array of PMTs. The tightly packed hexagonal PMT array (**Figure 3**) not only measures the total energy of each photon by summing the light deposited on the crystal, but also provides the spatial positioning of the detected photons. The location of each interaction is determined by combining the electrical signal from all PMTs in a logic circuit that weighs these signals appropriately and compares the relative amplitudes of signals resulting from each PMT.

Although PMTs have been in use for a number of years, their low quantum efficiency significantly limits both the energy and the spatial resolution of the camera, their output is sensitive to changes in temperature and magnetic fields, and they are bulky and expensive. Recently, a number of alternative solutions have been proposed ranging from position-sensitive tubes and hybrid PMTs to semiconductor avalanche photodiodes.

The last component of the camera is a computer or a workstation. First, it is used to specify acquisition parameters of the study such as the number and size of detector bins, the number of projection angles, the temporal duration of each view, and other features related to the motion of the gamma camera. During acquisition, the energy signal from the camera multichannel analyzer is analyzed in order to restrict the range of photons that are used to create the image. This is done by defining one or more energy window(s) corresponding to the photopeak energy of the radiotracer. Next, the computer digitizes and stores the data that passed the energy test, assigning

each event to a particular bin in the acquisition matrix. Finally, the computer is used in image reconstruction, which often includes different compensation procedures (resolution recovery, attenuation, and scatter correction) and digital filtering. At the last stage, different image

analysis procedures may be employed, aiming at 2D or 3D visualization of the measured and reconstructed distribution of the radiotracer.

Next Generation of NM Systems

The main limitations of NM imaging are the low sensitivity and poor resolution of the Anger cameras currently in use. To address these problems, a number of new systems have been investigated, often aiming at specific diagnostic applications. More importantly, recent progress in detector technology prompted the development of cameras that use CZT solid state detectors. These small pixelized detectors, initially used only in small animal cameras, are now slowly migrating into cardiology applications. Often in these new systems, the detectors do not move; the tomographic views are instead obtained using static or moving collimators with multiple openings.

The CardiArc camera (**Figure 4(a)**) uses stationary CZT detectors forming a 180° arc. A pinhole-type collimation is provided by a combination of a lead plate with a number of vertical slits, bent to fit the shape of the detector, and a series of horizontal slats placed behind this plate. The patient sits upright and tomographic data are obtained by moving the slits relative to the detectors. The high sensitivity and resolution of the system allow for two to three times shorter scans than with traditional cameras.

A second stationary solid state system is a compact cardiac camera, D-SPECT (**Figure 4(b)**), which uses nine columns of pixelated CZT detectors. In front of each detector column, a tungsten collimator with wide holes is placed. The columns sweep back and forth collecting photons with a sensitivity which is almost 10 times better than that of the conventional Anger system and which has up to twice the resolution.

Figure 4 Some examples of modern cardiac cameras using CZT detectors: (a) CardiArc, (b) D-SPECT, and (c) Alcyon. Photos are courtesy of CardiArc, Inc. (a), Spectrum Dynamics (b), and GE Healthcare (c).

Another cardiac SPECT system has recently been introduced by GE Healthcare using Alcyon detector technology (**Figure 4(c)**). The detectors are composed of stationary arrays of pixilated CZT modules arranged in 180° geometry and utilize focused collimation to optimize data acquisition from the myocardium. Preliminary evaluations indicate that spatial resolutions of 5 mm are obtainable with acquisition times of 3–5 min in typical clinical imaging situations. This technology is designed to be compatible with current GE CT systems in an integrated configuration to acquire transmission maps for attenuation correction, calcium scoring, and coronary CT angiography.

All these new systems claim to have much improved sensitivity and resolution allowing for much shortened cardiac scan duration. However, clinical verification of these claims is difficult. Even more difficult is proper evaluation of the accuracy and quality of their images, especially since they all require specialized data processing and use nonstandard image reconstruction algorithms.

Compton Cameras

To overcome the resolution and sensitivity limitations imposed by lead collimators, a system based on the principle of Compton scatter has been proposed. It uses the well-known formula that relates the energies of the

initial and secondary photons and the scattering angle. This approach, named electronic collimation, has already been successfully applied in astronomy.

A Compton camera consists of two energy- and position-sensitive detectors, working in coincidence mode. When an incoming photon undergoes Compton scatter in the first detector and is absorbed in the second detector (**Figure 5**), the measurement of the deposited energies and positions of these two interactions allows the user to define a conical surface that corresponds to all possible directions of the original photon. This by itself is not sufficient to determine the exact position of the source. Detection of multiple photons emitted from the source leads to the generation of several conical surfaces. Image reconstruction corresponds to identification of their intersection points, which is a much more complex problem than in the standard SPECT system. Other Compton camera difficulties are related to the Doppler effect, which for low-energy photons seriously affects the accuracy of measured energies and positions. Further problems exist with the design of the camera itself, including selection of the most appropriate detector materials and very complex camera electronics.

Physics Effects Limiting Quantitative Imaging

As photons pass through the tissue, they may undergo Compton or, to a lesser degree, Rayleigh scatter or be

Figure 5 The principle of electronic collimation. A photon originating from the decaying nucleus undergoes Compton scatter in the first detector (FD) and is absorbed by photoeffect in the second detector (SD). Information about the positions of each detection and deposited energies allow the definition of a conical surface on which the original nucleus is located.

totally absorbed through the photoelectric effect. In this context, the attenuation of photons in the patient body refers to the fraction of photons that are completely removed or diverted from their original path and that do not get detected. This may be caused by photoelectric absorption in the tissue or Compton scatter in which a photon's energy and its direction of propagation change. For large scattering angles, this energy decrease is also large; thus, the scattered photon may be eliminated by using the energy window preset on the camera. However, some of the scattered photons are still accepted by the camera electronics. They are usually recorded in an incorrect area of the detector, providing false information about the source location and intensity. The number of scattered events in SPECT studies may be as high as 20–30% of total recorded photons.

The relative importance of attenuation and scatter may be different in different studies as these effects depend strongly on the energy of the imaged photons, the distribution of the attenuating medium, and the characteristics of the imaging system. In general, the probability of attenuation and scatter in an object may be represented by its attenuation map. Such maps may be obtained through transmission scans performed using tomographic acquisition with an external radioactive source or with an X-ray device included as a part of the SPECT/CT system. Based on the information about tissue density contained in the patient's attenuation map, the effects of attenuation and scatter may be compensated for when using iterative reconstruction methods.

SPECT/CT Systems

Although they provide functional information very useful in diagnosis, SPECT images have poor resolution and often show few anatomical features, making the localization of organs or tumors difficult. Additionally, without proper corrections, SPECT images lack quantitative accuracy. In contrast, CT images provide anatomical details with high resolution but contain no or only limited functional information. By fusing SPECT images with corresponding CTs, both anatomical and functional information can be viewed simultaneously and CT attenuation maps can be used for SPECT quantitation.

Increasingly popular hybrid SPECT/CT systems (see **Figure 1(b)** and **1(c)**) offer the possibility to perform sequential NM and CT scans, using the same camera without ever moving the patient. Although the studies are done almost simultaneously and therefore should provide perfectly registered information about the anatomy and function of a patient, there are still problems with patient movement between and during scans. Additionally, these high-resolution images show clearly the need for further correction for patient breathing and heart beating. Investigated methods vary from, for

example, using tracking devices (reflecting markers and optical cameras) to software-only registration techniques.

Image Reconstructions

The processes involved in the acquisition of SPECT projections Y from an activity distribution λ can be described by the following equation:

$$Y = C\lambda$$

The system matrix C represents the probability that a photon emitted from a particular location in the object is detected by a specific projection bin. The reconstruction of a SPECT image, which represents an estimate of the original activity distribution $\lambda_{\text{estimate}}$, should therefore involve an inverse of the equation:

$$\lambda_{\text{estimate}} = C^{-1}Y$$

Usually, however, the system matrix C is very large, and the acquired data are contaminated with statistical noise, so the inverse problem is difficult, if not impossible, to solve as the solution may not exist or may not be unique.

Filtered Backprojection Reconstruction

Filtered backprojection (FBP) is an analytical technique that employs a simple model of SPECT imaging. It assumes that the number of photons collected in each detector bin correspond to a 1 D line integral through the activity distribution along a line perpendicular to the detector surface. Mathematically, this process corresponds to performing a Radon transform on the data. If the activity distribution being imaged is $\lambda(x, y)$, then the number of counts $Y(s, \theta)$ in the projection bin s at angle θ can be written as:

$$Y(s, \theta) = \int \lambda(x, y) dl$$

where $s = x \cos \theta + y \sin \theta$ and l is a vector perpendicular to the detector surface from the detector pixel position s through the activity in the object. The backprojection procedure redistributes the counts from each projection bin back into the image space along the lines l through the object. The point of intersection of all the backprojected lines corresponds to the potential source location. **Figure 6** shows the schematic representation of the Radon transform operation corresponding to data acquisition by Anger camera.

The true activity distribution can be recovered only if projections are acquired for an infinite number of angular views. Additionally, the projection data must be convolved with a sine function in the space domain or multiplied by a ramp filter when the Fourier domain is used. Mathematically, the ramp filter is related to the

transformation to polar coordinates:

$$|r| = \sqrt{x^2 + y^2}$$

The projection theorem (central slice theorem) provides the exact answer to the inverse Radon transform problem stating that the set of 1D Fourier transforms of the Radon transform of a function is equal to the 2D Fourier transform of that function.

FBP is the most common method used for clinical SPECT reconstruction as it is fast and much less computationally demanding than iterative algorithms. However, there are many problems associated with its use. As the ramp filter tends to amplify the noise, additional filtering is used, resulting in decreased resolution of the

Figure 6 A schematic representation of the Radon transform operation corresponding to data acquisition by Anger camera.

image. The limited number of projections creates a streak artifact. The most significant weakness of FBP is its inability to model the physics of the acquisition process or statistical nature of radioactive decay.

Iterative Reconstructions

Iterative reconstruction techniques perform a recursive search for the best estimate of the activity distribution, which corresponds to the measured projection data and a particular model of the SPECT data acquisition process. Their main advantage is that effects such as photon attenuation and scatter, as well as resolution loss due to collimator blurring, can be included directly in the system model.

An iterative algorithm begins with an initial guess of the original activity distribution λ° . The system matrix C is used to project λ° giving a set of the projections $C\lambda^\circ$. This step is called a forward projection. These new projections are compared to the measured projections, and a new set of corrected projections is calculated and backprojected into the image space. This process, presented schematically in **Figure 7**, is repeated several times successively providing new estimates of activity distribution that, with each iteration, more closely represent the actual truth. Besides modeling of the acquisition process, iterative reconstructions may include regularizers that enforce some *a priori* knowledge about the object being imaged, for example, knowledge of the smoothness of activity changes within the body, or the

Figure 7 The principle of iterative reconstruction of a tomographic image.

Poisson distribution of the count statistics in the projections.

Although different iterative algorithms have been developed for medical image reconstructions, the maximum likelihood expectation maximization (MLEM) remains the most popular. This approach implicitly assumes Poisson distributed statistical noise in the projections and seeks the most likely activity distribution that is consistent with the measured projections. The likelihood function is maximized when the difference between the estimated and the measured projections is minimized. Mathematically, the MLEM algorithm is described by the following equation:

$$\lambda_j^{n+1} = \frac{\lambda_j^n}{\sum_{i=1}^N C_{ij}} \sum_{i=1}^N C_{ij} \frac{Y_i}{\sum_{k=1}^M C_{ik} \lambda_k^n}$$

where λ_j^{n+1} is the estimate of activity in voxel j after the n th iteration, Y_i the number of counts recorded in projection pixel i , C_{ij} the system matrix element for those values of i and j , and N is the number of projection pixels. The denominator of the summed term is the forward projection, a calculation of the estimated value of projection pixel i summed over M , all voxels in the reconstructed object.

To speed up calculations, block iterative methods are used where each iterative update uses only a subset of all projections. Since the image estimate is updated several times during a complete block iteration, a good estimate of the original activity distribution can be reached using a much smaller number of iterations. Ordered subset expectation maximization (OSEM) is the block iterative method applied to the MLEM algorithm.

The MLEM algorithm has a number of advantages over analytical methods such as FBP. These include the ability to model the emission and detection processes and the statistical noise in the projection data. Further, it allows for the application of regularizers and constraints on possible solutions based on *a priori* knowledge about the activity distribution in the object. One of the

disadvantages of the MLEM algorithm is that it does not converge to a unique solution in the presence of statistical noise in the projection data, but rather continues to iterate attempting to fit best the activity distribution to the noise in the projection data. There is no obvious criterion indicating when the iterative process should be stopped.

Introduction

All group 14 elements – except germanium – share, from the viewpoint of the NMR spectroscopist, one rather important feature: they all have at least one isotope with a spin of $\frac{1}{2}$ that is a minor component of the isotopes of the element. The most important element in this group is, of course, carbon and most people are familiar with obtaining and interpreting ^{13}C NMR spectra. Consequently a comparison with the situation of carbon might be helpful (Table 1).

An inspection of Table 1 shows that ^{29}Si has a higher share of the isotopic mixture but the absolute value of the magnetic moment is slightly lower than that of ^{13}C . This leads to a lower resonance frequency. A complication arises from the fact that the spin and magnetic moment are antiparallel, leading to negative sign of γ .

The chemistry of silicon is very different to that of carbon and in organic compounds there is usually a lower

silicon content than carbon. These shortcomings meant that silicon NMR spectroscopy had a slow start. After the first report by Lauterbur and co-workers in 1962 there had been only a few papers per year. But this has now changed dramatically and one collection of ^{29}Si chemical shifts now contains about 9000 data sets. One area of special growth is ^{29}Si NMR measurement on solids. Here applications range from crystalline silicates over amorphous silica gels to silicon-containing surfaces and coatings.

Measuring ^{29}Si NMR

Referencing

The established standard compound to calibrate ^1H and ^{13}C spectra is tetramethylsilane ($(\text{CH}_3)_4\text{Si}$ (TMS). As this substance contains silicon also, it is natural to use it as standard for Si NMR. Although TMS is an inert substance, has a low boiling point and a rather short relaxation time, its chemical shift is in the middle of the shift range of other organosilicon compounds and peak mis-assignments are possible. Two strategies to circumvent this problem have been developed. The first is the use of secondary standards. Table 2 lists a number of those used in the literature.

M_8Q_8 , shown in Table 2, has a lower symmetry in the solid state and its resonances are split into several lines, but it is the common reference compound used as an internal standard for solid state Si NMR. The second tactic is to use no standard compound in the sample at all. The referencing is done externally relative to a separate sample that contains TMS in the same solvent as is used in the analysis sample.

Early reports of silicon NMR data employ the magnetic field definition of chemical shifts instead of the now universally accepted frequency-based one, resulting in a reversed sign for chemical shift data.

Pulse Sequences

In principle there are two cases to distinguish: many, especially inorganic, compounds contain only ^{29}Si as a useful magnetic nucleus. Here, single pulse experiments are applicable only. Because of the rather slow relaxation in such compounds, a 30° pulse is used with a repetition rate of about 20 s.

On the other hand, silicon compounds with organic side-groups usually have resonances split into many lines

by spin–spin couplings with the protons. These are normally removed by decoupling. Because of the negative gyromagnetic ratio of ²⁹Si the nuclear Overhauser effect (NOE) is also negative, leading to negative signals with an enhancement factor of $\eta_0 = -2.52$ if the relaxation is dominated by dipolar interactions with the protons. With few exceptions, the relaxation path is divided between the dipolar term and others – mostly the spin–rotation interaction. This results in much lower enhancement factors and even null signals. This can be overcome by:

1. Doping of the sample with a shiftless relaxation agent such as Cr(acac)₃ at a concentration of $\sim 10^{-2}$ mol dm⁻³. However, such a compound might react with the sample and it is also difficult to remove.
2. Inverse gated decoupling. Here the proton decoupler is switched off during a recovery time (three to five times the silicon relaxation time). The advantage of not contaminating the sample is offset by an ineffective use of spectrometer time.
3. The use of pulse programmes such as insensitive nuclei enhanced by polarization transfer (INEPT) or distortionless enhancements by polarization transfer (DEPT). There are two advantages in using these programmes. The first is a signal enhancement by population transfer from the protons that depends on the number of coupling protons. A good review has been given by Blinka et al. The second advantage is the removal of the background signal caused by the silicon content of the probe. However, these techniques depend on the proton–silicon coupling constant and as these can cover a considerable range in organosilicon compounds this can lead to unexpected results. An example is shown in **Figure 1** where a ²⁹Si INEPT spectrum of an octasilsesquioxane is displayed. Because the siloxane skeleton consists of a cube with silicon on the vertices and oxygen on the edges of the cube, the cage can only rotate as a whole. This way the silicon relaxes almost solely by the spin–dipole path.

The relaxation times are rather long and the signals very narrow.

The NMR of solids differs from that of liquids insofar as spatial interactions are not averaged out by Brownian motion. The NMR resonances are therefore so broad that chemical shifts and indirect spin–spin couplings are not resolved. There are different ways of handling solid state NMR problems. Here is not the place to cover all of them. The most common presently used method starts with a powder of crystalline or amorphous silicon compound. In the absence of nuclei with a strong magnetic moment such as ¹H or ¹⁹F or ions with unpaired electrons, the source of broadening of the signals comes from the fact that the chemical shift is a tensor. This chemical shift anisotropy (CSA) can be removed by fast spinning (3000–15 000 Hz) around an angle of 54°44' (magic-angle spinning, MAS). The CSA is then reduced to a series of sidebands spaced at the rotational frequency and with an intensity profile governed by the CSA. By rotating the sample fast enough, these sidebands can be moved out of the region of the chemical shifts of the sample. On the other hand, by rotating slowly, the CSA can be determined. The *direct* spin–spin coupling between ²⁹Si nuclei is small because the magnetic moment is small and the average distance between ²⁹Si nuclei is large because the abundance of ²⁹Si is just 4.7%. For most crystalline silicates, single resonance NMR spectroscopy under MAS is the best choice. Depending on the quality of the crystals, narrow peaks with line widths between 0.1 to 3 ppm can be obtained. In addition to single pulse spectroscopy, incredible natural abundance double quantum transfer experiment (INADEQUATE) or 2D correlation spectroscopy (2D-COSY) can be carried out to determine the connectivity of the silicon atoms.

Organosilicon compounds contain hydrogen and the strong magnetic moment of ¹H leads to very broad lines in the solid state by *direct* proton–silicon spin–spin interaction. This coupling is usually removed by high power decoupling of the protons. The spin coupling with protons offers the opportunity to obtain stronger signals by the cross-polarization (CP) technique. The connection between the proton and silicon spins is possible if both spins are rotating with the same speed around the magnetic field, i.e. $\gamma_H B_{1H} = \gamma_{Si} B_{1Si}$ (spin locking, Hartmann–Hahn condition). The most effective time for this spin locking is determined by the proton–silicon distance. Because of the higher incidence of protons the ¹H relaxation time is usually shorter, so that besides the inherently stronger signals the pulse repetition rate can be faster.

²⁹Si Chemical Shifts

General Features

In principle, two kinds of silicon compounds are possible. The first kind, derived from divalent silicon [Si(II)], is

Figure 1 ²⁹Si NMR spectrum of (3-mercaptopropyl)hepta(propyl)octasilsesquioxane. The small signals are due to ²⁹Si–²⁹Si coupling.

normally thermodynamically unstable. Some exist at high temperatures or may be trapped using cryogenic temperatures. However, a few are stable enough to be handled at room temperature, but the small number of examples does not allow a general definition of a specific range of chemical shifts. Nevertheless, derivatives with a high coordination number are strongly shielded. Thus, for instance, decamethylsilicocene, $[(CH_3)_5]_2Si$, has a shift of -398 ppm, the highest shielding measured so far. Another situation where Si(II) seems to be stable is between two nitrogen atoms, as in [1]. The silicon is then rather deshielded with values of the chemical shift between $+78.3$ and $+96.9$ ppm.

The majority of the ²⁹Si NMR data reported involve derivatives of Si(IV). The most deshielded silicon ($+268.7$ ppm) has been reported for [2], the most shielded for SiI₄ (-351.7 ppm), but the majority of shifts are found between -200 and 150 ppm. As with the other heavier nuclei, the chemical shift depends primarily on the coordination number of the silicon in such a way that a low number of substituents around the silicon leads to deshielding (e.g. disilylenes: 13 to 175 ppm) and a high coordination number gives high negative numbers (e.g. sixfold coordination: -198 to -135 ppm). The regions of chemical shifts for some important classes of silicon compounds are depicted in **Figure 2**.

There have been several proposals to rationalize silicon chemical shifts. Most of them centre on the charge on the silicon atom. Ernst and co-workers observed that the chemical shifts follow a parabolic curve if plotted against the sum of the electronegativities of the substituents of the silicon. Thus, above the sum of electronegativities of 9.5 , a further increase of the electronegativity leads to an increase of the shielding. However, a decrease of shielding is observed if this sum is below 9.5 .

Figure 2 Ranges of chemical shift of selected classes of silicon compounds. (R is an arbitrary organic ligand, Y = F or OR.) See also **Figures 5, 6 and 8**.

Radeglia and co-workers consider that the charge on the silicon determines not only the shielding but also its distribution. This is due to the paramagnetic contribution to the shielding constant. They define a reduced shielding constant σ^* on the basis of the valence shell p orbitals of the silicon:

$$\sigma^* = \frac{\sigma_p}{\sigma_{p_0}} = \frac{P_u \langle r^{-3} \rangle_p}{P_u \langle r^{-3} \rangle_{p_0}} = P_u^* R^* \quad [1]$$

where the index 0 pertains to a situation in which all electrons are distributed evenly around the silicon. The terms P_u^* and R^* are then calculated to various degrees of sophistication. One approach uses Slater-type orbitals and Slater rules; R^* is then given by:

$$R^* = \frac{\langle r^{-3} \rangle_p}{\langle r^{-3} \rangle_{p_0}} = \left(1 + 0.35 \frac{f q_{\text{Si}}}{Z_0(\text{Si})} \right)^3 \quad [2]$$

with $Z_0(\text{Si}) = 4.15$, $f = 0.2135$ as an empirical factor and q_{Si} stands for the charge on the silicon atom:

$$q_{\text{Si}} = 4 - \sum_{i=A}^D b_i \quad [3]$$

The bond polarity b_i , calculated from their electronegativities, is summed up over all four substituents (A to D) on the silicon. The term P_u takes elements of the bond order matrix around the silicon atom into account, using the electronegativity as a measure of electron distribution:

$$P_u^* = \frac{P_u}{P_{u_0}} = \frac{1}{2} \sum_i b_i - \frac{1}{6} \sum_{i>j} b_i b_j \quad [4]$$

Figure 3 The effect of successive substitution on ²⁹Si NMR chemical shifts. (●) (CH₃)_{4-n}Si(OCH₃)_n; (◆) H_{4-n}SiF_n.

The σ^* values so calculated do not give chemical shifts directly but have to be fitted empirically. Nevertheless, it is remarkable that the shape of the curve of ²⁹Si chemical shifts as a function of the number of substituents (**Figure 3**) is reproduced by such calculations. The literature and a discussion of this procedure and other aspects of silicon chemical shift interpretation have been given by Marsmann (see Further Reading section). Empirical aspects of chemical shifts of different classes of some silicon compounds only are given briefly below.

Organosilanes

Silicon surrounded by four carbon atoms gives resonances between $\sim +100$ and -107 ppm. As expected, shifts of silicon with aliphatic substituents are clustered around 0 ppm. Increased shielding is found if the ligands around the silicon atom have π bonds in the β position and thus the centre of shifts is moved to -35 ppm if silicon is connected to four sp^2 -hybridized carbons. Very high shielding is observed for silicon in silacyclopropanes (~ -60 to -40 ppm) and silacyclopropenes [3] (-87 to -106 ppm). The influence of π orbitals is discussed in the later case. The strong deshielding for the bridge silicon in silanorbornadienes [4] (76–98 ppm) is also attributed to a σ – π interaction.

Siloxanes and Silicates

One of the main interests in silicon NMR is because it allows distinction between the building units of a polysiloxane. A sketch of an imaginary polysiloxane to make the concept of building units and their nomenclature clearer is given in **Figure 4**. If the substituent R is not a methyl group, appropriate notation for that substituent is added as a superscript. A collection of chemical shift ranges of such building units has been published by Williams and is shown here as **Figure 5**.

Ring strain has a marked effect on the shifts. This can be seen for example, with dimethylsiloxanes in (**Table 3**). In polysiloxanes with different middle groups, it is possible to distinguish the triad and even the pentad structures in the backbone of the polymer.

Approximately the same behaviour, but with a smaller range, is observed if R = OH or O[−] in silicates. However, as they are now all Q units, they are distinguished by a superscript *n* (*n* = 0–4), indicating the number of non-connecting oxygen atoms around the silicon. For instance, Q² designates a middle group with two connecting and two non-connecting oxygens. In aqueous solution there are fast equilibria between ionized and unionized forms. This causes a dependency of the chemical shifts of the building units on the pH. As the acidity of the building units differs and the existence of individual silicate ions is pH-dependent, this makes the analysis of such aqueous silicate solutions very difficult and some resonances are still not assigned. To make things a little more manageable, the signal of the monosilicate Si(OH)₄ or its corresponding ions is taken as a secondary shift standard. A rough conversion into the TMS scale can be obtained by adding −71.3 ppm. The use of highly ²⁹Si-enriched material proved to be very successful and a number of individual ions could be identified by selective decoupling and ²⁹Si, ²⁹Si COSY experiments. It was found that silicate ions in solution

Figure 4 Building units of a hypothetical polysiloxane.

consist mostly of small fused rings. A collection of the shift ranges of acyclic silicic acid ions and esters is given in **Table 4**. Ring strain again leads to deshielding, so that, for example, the signal of the middle groups of trimeric rings can be found close to the end groups and that of their trifunctional branching close to the region of middle groups. The use of Si NMR of solid silicates provides valuable information. The isotropic shifts in silicates follow similar rules to aqueous silicates. The low CSA value of <100 ppm makes the MAS spectra of silicates easy to observe. There are, however, some differences. In crystalline silicates, the shifts also depend on the crystallographic symmetry, which can be lower than in the dissolved state. The most famous example is that of M₈Q₈, which gives two sharp lines in solution but splits into seven signals in the solid (**Table 2**). The Si–O–X angle dependence of shifts – not observable for solutes – is responsible for the spread of ~30 ppm for the disilicate from ~−70 to −100 ppm compared with a region of about 4 ppm for the end groups in aqueous silicates. It is possible to determine the Si–O–X angles on the basis of chemical shifts. One of the triumphs of ²⁹Si MAS NMR spectroscopy was the determination of the distribution of silicon and aluminium in aluminosilicates, e.g. zeolites. Silicon chemical shifts move ~5 ppm to higher field if an Si–O–Si bond is exchanged for an Si–O–Al, as can be seen from **Figure 6**. Although it is not

possible to disprove a statistical distribution of Si and Al in the framework, it seems that the Al sites are highly ordered and that the Loewenstein rule is observed, i.e. that no direct Al–O–Al connections in aluminosilicates are stable. Another field for ²⁹Si MAS NMR is the characterization of glasses, silica-gels and their organically modified surfaces which are used in chromatography or catalysts. Here the silicate framework is amorphous, i.e. although each silicon is surrounded by four oxygen atoms, there is no long-range order. Compared with the signals of well-crystallized silicates this kind of material gives very broad signals with almost no features. In silica-gels and similar materials the non-connecting oxygens are in the form of OH or OR groups. This allows CP MAS NMR spectra to be obtained. **Figure 7** shows a CP MAS spectrum of a silica-gel with an organically modified surface.

Trimethylsilyl Derivatives

The (CH₃)₃Si– moiety is a very useful fragment in several kinds of chemistry. It is used in organic synthesis because it can direct reactions along a particular path or act as a protecting group. In addition, it can be split off by gentle methods. The exchange of the protons in OH or >NH groups for a (CH₃)₃Si– group increases the volatility and the solubility in organic solvents. This has many applications in analytical chemistry. Schraml showed that the trimethylsiloxy group is useful as an NMR tag for the

analysis of natural products such as sugars, lignins, etc. Therefore, silicon chemical shifts for these types of compounds are very common in the literature. About a quarter of all reports of silicon NMR shifts deal with them. The regions of chemical shifts for trimethylsilylated compounds are given in **Figure 8**.

The trimethylsilyl group bound to a carbon atom has relatively clear-cut regions. If the carbon is an aliphatic one, most of the resonances appear between – 1.6 and + 3.8 ppm. If the carbon is substituted with electro-negative elements, more positive values are possible. A sp²-hybridized carbon results in shifts to higher fields and the resonances are now clustered around – 3.8 ppm. The silicon is more shielded if the carbon is a ring member (~ – 11 ppm). In (CH₃)₃SiN– derivatives the spread of chemical shifts is small if the nitrogen is aliphatic (– 3.3 to 17.3 ppm), while it is more diverse if the nitrogen has a double bond. If the nitrogen is in an aromatic ring system, a compact region with positive values is discernible (3 to 18 ppm). However, no clear pattern emerges for other environments of this type.

A wealth of data exist for the trimethylsiloxy group. The greatest spread of data is found for the trimethylsilyl esters of acids. There is a linear correlation between the silicon chemical shift and the strength of the acid. The overlapping regions for the shift values of alcohols make further experiments necessary for an assignment. One procedure is the use of hydrogen–silicon couplings to the non-methyl part of the molecule. A review has been given by Schraml.

Polysilanes

An extensive review of this area has been presented by Williams. The structural principles of the poly-silanes are the same as those of the alkanes. Thus, the rules applied for alkanes were extended to the silanes. This approach after Paul and Grant was used by West and Stanislawski to derive eqn [5] for dimethylsilanes.

$$\delta_{Si(k)} = B + \sum_l A_l n_{kl} \quad [5]$$

with A_l the chemical shift parameter for the *l*th atom from the *k*th position and *n_{kl}* the number of atoms present in that position. The term *B* is constant (8.5 ppm) and A_l is – 25.8 ± 0.1 ppm for the α position, + 3.9 ± 0.05 ppm for the β position, + 1.2 ± 0.09 ppm for the γ position and

Figure 7 ²⁹Si MAS CP spectrum of a surface modified silica-gel. The signal strength is no indication of the concentration of the corresponding building group. Peak 1: (CH₃SiO-; peaks 2,3: T², T³ of the functional group RSi(O-)₃; peaks 4,5: Q³, Q⁴ of the silica-gel skeleton.

Figure 8 Regions of chemical shifts for trimethylsilylated compounds (R¹ = aliphatic, R² = unsaturated organic residue).

+0.2–0.01 ppm for the δ position relative to the silicon atom considered. This works well for end, middle and trifunctional branching groups but not so well for tetrafunctional branching and otherwise substituted silanes. Hahn used a similar concept to describe the shifts of silanes:

$$\delta_{\text{Si}} = -96.02 - 2.43a - 3.73a^2 + Bb + C \quad [6]$$

where -96.02 represents the idealized shift of mono-silane, a the number of silicon atoms in the α position, b

those in the β position, and B and C are the incremental shifts produced by the β and γ silicon atoms.

Silicon with a Coordination Number of Three

A coordination number of three is found for compounds in which the silicon extends a $p_{\pi}-p_{\pi}$ bond to a partner. The usual condition is that the two other ligands to the silicon are sterically demanding, such as a phenyl group with substituents in the *ortho* position. The assumption of a $p_{\pi}-p_{\pi}$ bond in disilylenes is supported strongly by the chemical shift anisotropy data obtained from solid-state silicon NMR measurements which are comparable to that of a $p_{\pi}-p_{\pi}$ carbon bond. Although little data exist for this class of silicon compound, it seems that all of them are deshielded compared with TMS. At present, compounds with a Si=C fragment have shifts between 13 and 144 ppm, where a silicon attached to the carbon leads to the higher numbers. Compounds with a Si=Si moiety resonate between 52 and 65 ppm and in a Si=P fragment the silicon resonances are found between 148 and 176 ppm. The spread of shifts is surprisingly low for simple transition metal derivatives of silylenes. Shift values range from 83.6 ppm for $(t\text{-C}_4\text{H}_9\text{S})_2\text{Si Fe}(\text{CO})_4$ to 142.1 ppm for $\text{ArHSi}=\text{MnCp}(\text{CO})_2$.

The Effect of Higher Coordination Numbers

Although the normal coordination number of silicon is four, the atom still acts as a Lewis acid, especially if the silicon is bound to electronegative ligands and hence coordination numbers of five and six are possible. However, because of equilibria it is not always possible to establish

the degree of higher coordination in solution. In this respect, couplings to other magnetic nuclei are of help. Thus for silatranes [5] – the largest group of fivefold coordinated silicon compounds measured so far – the additional bond to nitrogen could be assured by the observation of a small ²⁹Si–¹⁵N coupling (0.20–3.37 Hz). In addition, the difference between the shifts in solution and in the solid state is small (–1.0 to –5.1 ppm). It is estimated that the additional bond to the nitrogen results in an increased shielding of ~ –10 to –30 ppm. Shifts of silatranes have been observed between –107 and –59 ppm.

Diols and other oxygen-containing ligands can give rise to sixfold coordination. The mineral thaumasite displays resonances between –182.1 and –177.9 ppm. Complexes with diols have resonance lines between –197 and –135 ppm. Sixfold coordination is discussed here. The effect of putting two additional oxygen atoms in the coordination sphere is ~ –100 ppm upfield shift. The result is less pronounced if five oxygen atoms form the first ligand sphere around the silicon. Resonances are found between –131 to –120 ppm, giving an extra shift of ~ –50 ppm compared with tetraalkoxysilanes.

Fluorine is also capable of expanding the coordination sphere of silicon. Here the coupling between ²⁹Si and ¹⁹F can be used to confirm the number of fluorines around the silicon. Fluxional behaviour is often observed. The hexafluorosilicate anion (SiF₆^{2–}) resonates at a very high field (–191.7 ppm). More common are fivefold coordinated compounds measured in solution as well as in the solid state. The extra fluorine results in shifts to low frequencies between –28 and –80 ppm; the larger effect is observed in difluorides.

Donating solvents such as hexamethylphosphoramide or dimethylpropylurea give rise to upfield shifts which have been interpreted as caused by the formation of pentacoordinated complexes. The solvent shifts seem to follow Gutmann's donor number for solvents.

Transition Metal Derivatives

This has been a fast growing area but, owing to the very diverse situation for a silicon bound to a transition metal ion, only very rough trends can be distinguished so far. The most positive shift values arise from non-classical transition metal complexes such as [2]. The other limit is formed by a number of platinum complexes that display values between –90 to –29 ppm. Within a group of the

periodic table there seems to be a trend towards lower frequency on going to the heavier homologues. Some useful observations have been made by Pannell and Bassingdale for more conventional complexes where the silicon is connected to the metal by a single bond. Comparing the shift of the complex to that of a compound where the metal is exchanged by a methyl group, it is found that the silicon shifts are +40 ppm higher in the complex if the metal is Fe or Ru, but –13 to –39 ppm lower for Re.

Coupling Constants Involving ²⁹Si

All magnetic nuclei within a molecule interact, leading to line splittings or sometimes line broadening. There are two cases to consider:

1. The silicon interacts with an abundant isotope, e.g. ¹H, ¹⁹F or ³¹P. Then the silicon resonance is split according to the well-known rules for spin–spin interaction.
2. The silicon couples with another dilute spin such as ²⁹Si itself or, for example, ¹³C or ¹⁹⁵Pt. The coupling then gives rise to doublets to the left and right of a strong centre line in the form of satellites.

For a complete collection of coupling constants, the relevant reviews should be consulted (see Marsmann, and Schraml and Bellama in the Further reading section). Some frequently encountered coupling situations for silicon are discussed below.

Silicon–Hydrogen Couplings

The coupling with hydrogen is also visible in proton NMR spectra and this was used even before ²⁹Si NMR spectroscopy was feasible. Because of the many and complex splittings arising from silicon–proton interactions, the coupling is usually removed by decoupling in the spectra of organosilicon compounds. Of the three possible pathways, the Fermi contact term is the most efficient. Therefore, because of the negative gyromagnetic ratio of ²⁹Si, the sign of the coupling over one bond is negative, but absolute values only are given in the following. The magnitude of the coupling then depends on the s orbital density between the hydrogen and the silicon. Semiempirical and empirical relationships have been developed by several authors, e.g.

$$^1J(\text{Si}, \text{H}) = 725\alpha_{\text{Si}}^2 + 15.9 \quad [7]$$

$$^1J(\text{Si}, \text{H}) = 969.7\alpha_{\text{Si}}^2 + 5.9N_{\text{P}} - 41.0 \quad [8]$$

$$^1J(\text{Si}, \text{H}) = 810\alpha_{\text{Si}}^2 + 4.3N_{\text{P}} - 1.40N_{\text{Me}} \quad [9]$$

for compounds of the type H_nSiR_{4–n} (R = CH₃, C₆H₅; n = 1–3). Here α_{Si}² is the square of the s character of the

bond used by the silicon, N_P is the number of phenyl groups and N_{Me} is the number of methyl groups bonded to the silicon. On a purely empirical basis, there is a rough correlation between the electronegativity of the other bonding partners of the silicon and the magnitude of the coupling constant J in such a way that highly electronegative substituents favour a large value for $J(\text{Si}, \text{H})$. The range for the magnitude of coupling constants over one bond, $^1J(\text{Si}, \text{H})$, is between 74.8 Hz (H_3SiK) and 371.7 Hz (HSiF_3). An exception is the value of 420 Hz for the transition metal complex $\text{H}_2\text{Si}[\text{Mn}(\text{CO})_5]_2 \cdot 4\text{py}$.

Of the couplings over two bonds, $^2J(\text{Si}, \text{H})$, the most important is for the $\text{Si}-\text{CH}_3$ fragment. Values range from 6.0 to 9.5 Hz in most cases. An exception is $(\text{CH}_3)_3\text{SiLi}$ which has a value for $^2J(\text{Si}, \text{H})$ of 2.8 or 3.5 Hz.

The large values of 2J found if the bonding goes over a transition metal have been interpreted as a sign of an agostic interaction, e.g. constants between 20 and 69 Hz for $^2J(\text{Si}, \text{Mn}, \text{H})$.

Silicon–Fluorine Couplings

For one-bond couplings, $^1J(\text{Si}, \text{F})$, typical values lie in the 167–488 Hz range, if only compounds with a coordination number of four for the silicon are considered. The decreased share of the s orbital per bond leads to lower values for the coupling in compounds with higher coordination numbers for silicon, e.g. 131–300 Hz for five-fold and 108–182 Hz for sixfold coordinated silicon compounds.

Silicon–Phosphorus Couplings

In silylphosphines, it was possible to rationalize the one-bond phosphorus–silicon coupling constants $^1J(\text{P}, \text{Si})$ according to an empirical equation:

$$^1J(\text{P}, \text{Si}) = 26.3 + 8u + 5v - Z\omega \quad [10]$$

where 26.3 Hz is the value for the reference compound H_3SiPH_2 , u the number of silyl groups, v the number of methyl groups substituting $\text{P}-\text{H}$ and w the number of methyl groups substituting the $\text{Si}-\text{H}$ bonds. The empirical factor Z lies between 3.3 and 5. A silicon–phosphorus double bond gives a splitting of 149 to 155 Hz.

A body of data exists for two-bond silicon coupling to phosphorus with an intervening nitrogen. Very low values are observed if the nitrogen is sp^3 -hybridized, but values of $^2J(\text{Si}, \text{N}, \text{P})$ between 8 and 42 Hz are typical for nitrogen with a double bond.

Silicon–Carbon and Silicon–Silicon Couplings

Both ^{13}C and ^{29}Si count as magnetically dilute isotopes. Therefore couplings are found only in the form of small

satellites with an intensity of $\sim 0.5\%$ (^{13}C) or 2.3% (^{29}Si) on both sides of a strong central line. The Fermi contact term should be the dominant pathway to transfer magnetization between silicon and carbon. Thus the interaction depends on the s-electron density on both nuclei. The following semiempirical equations have been discussed:

$$^1J(\text{Si}, \text{C}) = 555.5\alpha_c^2\alpha_{\text{Si}}^2 + 18.2 \quad [11]$$

$$^1J(\text{Si}, \text{C}) = -1227.77^2_{\text{SiSiC}} + 26.0 \quad [12]$$

where α_c^2 and α_{Si}^2 are the square of the s character in the bonds that connect the carbon and the silicon and P_{SiSiC} is the bond order element pertaining to the $\text{Si}-\text{C}$ bond.

Values for $^1J(\text{C}, \text{Si})$ are between 44 and 107 Hz. The high end is characteristic of silicon bonded to substituents of high electronegativity and sp^2 -hybridized carbon. For a silicon–carbon double bond a value of 83.7 Hz has been reported.

Silicon–silicon coupling constants over a single bond range between 23 and 186 Hz. For $\text{Si}=\text{Si}$ double bonds, values between 155 and 158 Hz are characteristic. This is somewhat higher than the values found for diarysilanes (~ 85 Hz). The $^2J(\text{Si}, \text{Si}, \text{Si})$ in stress-free situations lies in the 3–13 Hz range, but in polycyclic silanes ranges between 14 and 24 Hz. Because ring strain seems to decrease one-bond coupling constants, both types of constants are difficult to distinguish in that class of silanes. Two-bond couplings over oxygen are generally small. $^2J(\text{Si}, \text{O}, \text{Si})$ data are between 0.5 and 14 Hz. The lower end is typical of silsesquioxanes and the larger values are found for $\text{Si}-\text{O}-\text{Si}$ fragments in the skeletons of trimethylsilyl silicates.

Spin–Lattice Relaxation

For an isotope with a negative gyromagnetic ratio it is even more important to know of the pathways by which the ^{29}Si dissipates its energy from the excited state to the surroundings (lattice). In principle there are five paths, and the total spin–lattice relaxation time can be calculated from the contributions arising from each one:

$$\frac{1}{T_1} = \frac{1}{T_1^{\text{DD}}} + \frac{1}{T_1^{\text{SR}}} + \frac{1}{T_1^{\text{CSA}}} + \frac{1}{T_1^{\text{SC}}} + \frac{1}{T_1^{\text{E}}} \quad [13]$$

Here T_1^{DD} is the dipolar, T_1^{SR} the spin–rotation, T_1^{CSA} the chemical shift anisotropy, T_1^{SC} the scalar and T_1^{E} the electronic contribution to the spin–lattice relaxation. At the heart of all relaxation paths is the formation of fluctuating magnetic fields.

Owing to the strong magnetic moment of the electron, T_1^{E} is very efficient. The extreme variation of T_1 in solids is explained by the effect of paramagnetic ions or

molecular oxygen. In solution, shiftless paramagnetic relaxation agents [e.g. Cr(acac)₃, 10⁻² molar] are used to shorten T_1 to ~ 10 s. Molecular oxygen also acts as a relaxation agent. It was calculated that for a solution saturated with oxygen at 1 bar, T_1^E is between 35 and 57 s. If other relaxation pathways are to be measured or a small line width is desired, paramagnetic impurities have to be removed. Paramagnetic ions that leach from the sample tube are removed by rinsing them with a chelating reagent (e.g. EDTA) before use. Oxygen is removed by bubbling argon through the sample or by vacuum techniques.

In the absence of unpaired electrons, the most efficient pathways for relaxation are the dipolar and the spin-rotation mechanisms. Because the interaction with protons is the most dominant one in this respect, the discussion will be restricted to this aspect. The dipolar term T_1^{DD}

$$\frac{1}{T_1^{DD}} = \hbar^2 \tau_c \sum \gamma_H^2 \gamma_{Si}^2 r_{SiH}^{-6} \quad [14]$$

then depends on the gyromagnetic ratios of the ¹H and ²⁹Si isotopes, the distance between them and a correlation time, τ_c (eqn [14]). Owing to the larger radius of silicon compared with that of carbon, dipolar relaxation is less efficient than in ¹³C NMR. Another aspect of the longer Si-H bond distance is that hydrogens placed farther apart in the molecule or on solvents can now also contribute to the relaxation process. The correlation time τ_c is the mean time the molecule, or a part of it, rotates one radian. This process is temperature dependent (Figure 9).

If in organosilicon compounds, the signal splittings caused by the coupling with the protons are removed by decoupling, then a modulation of the signal intensity occurs that is connected with the dipolar term. If the silicon relaxes by dipolar interaction with the protons only, then the signal intensity is multiplied by a factor of -1.52 from the nuclear Overhauser effect NOE:

$$\begin{aligned} \text{NOE} &= \frac{\text{signal intensity with irradiation of the protons}}{\text{signal intensity without irradiation}} \\ &= 1 + \frac{\gamma_H T_1}{12 \gamma_{Si} T_1^{DD}} \end{aligned} \quad [15]$$

The Overhauser enhancement factor η is calculated as

$$\text{NOE} = 1 + \eta \quad [16]$$

If the dipolar mechanism is the only pathway, then η becomes $\eta_0 = -2.52$. Otherwise the share of the dipolar relaxation on the whole relaxation process can be calculated by:

$$T_1^{DD} = -\frac{2.52 T_1}{\eta} \quad [17]$$

Therefore, in the unfortunate case of $\eta = -1$, the signal intensity is zero. The other major relaxation mechanism involves spin-rotation interaction. The rotation of a

Figure 9 ²⁹Si Spin-lattice relaxation in TMS. (●) T_1^{DD} ; (◆) T_1^{SR} , assuming $T_1^{CSA} \gg T_1^{DD}$. Reproduced with permission of the American Chemical Society from Levy GC, Cargioli JD, Juliano PC, and Mitchell TD (1973) *Journal of the American Chemical Society* 95: 3445.

molecule or a part of it generates a ring current through the electrons connected to it. By the tumbling motion of the molecules, fluctuating magnetic fields are produced. The spin-rotation relaxation time T_1^{SR} is given by

$$\frac{1}{T_1^{SR}} = \frac{2\pi I k T 2 C_{\perp}^2 + C_{\parallel}^2}{h^2 3} \tau_j \quad [18]$$

The correlation time τ_j is the angular momentum correlation time, the time the molecule changes its angular momentum, usually the time between collisions. The terms $C_{\parallel}$ and $C_{\perp}$ are components of the spin-rotation interaction tensor and I is the moment of inertia of the molecule. For small step diffusion, τ_c and τ_j are connected by the Hubbard relation:

$$\tau_c \tau_j = \frac{I}{6kT} \quad [19]$$

Because for any given molecule in eqn [17] all data are constant except T and τ_j , this results in a temperature dependence which is the reverse of that for T_1^{DD} (Figure 9). At high temperatures the relaxation process is dominated by the spin-rotation contribution and at low temperatures by the dipolar part. In between is a maximum value for the total relaxation time T_1 . Another consequence is that the intensity of proton decoupled ²⁹Si spectra is temperature dependent.

Typical values for the relaxation times for organosiloxanes are between 35 to 205 s. Lower values are found for aqueous solutions of silicates (0.3–4.6 s), higher ones for silicon compounds without protons, e.g. chlorosiloxanes (53–352 s).

Symbols

e	electron charge
f_a	atomic scattering factor
i	$\sqrt{-1}$
r	radius-vector
R	discrepancy factor between the observed structure factors of reflections (F_o) and those calculated from the structure (F_c)
r_g	thermal average internuclear distance
$\langle u^2 \rangle$	mean square amplitude of oscillations
κ	expansion–contraction parameter
ν	frequency
ρ	electron density
σ	estimated standard deviation (esd)
∇	Laplacian

Single crystal X-ray diffraction is the main source of information on the geometrical structure of molecules and molecular solids, including bond distances (and hence bond orders), bond angles, shapes of coordination polyhedra, conformations of flexible molecules, as well as intermolecular contacts. It can always distinguish between configurational isomers (e.g. *cis* or *trans*), and often optical isomers (enantiomers), too. The enormous and fast-growing mass of X-ray structural data defies any attempt to review it even in the most general way. Numerous compendiums and reference tables on these data have been published. In fact, X-ray crystallography provides the main bulk of data for any book on structural chemistry and the theory of the chemical bond. More recently, computerized structural databases have given easy access to all available X-ray crystal structures and sophisticated means of extracting from them necessary parameters, performing statistical analysis of the data and finding regularities (structural correlations). On a higher level of precision, it is possible now to determine not only the atomic positions, but also the entire map of electron density in a crystal, visualizing concentrations of bonding electrons and lone electron pairs, determining directly atomic charges, electrostatic potentials, etc. The analysis of the displacement parameters of atoms is also of much importance, both to improve the accuracy of molecular geometry determinations and to understand the dynamic behaviour of crystal structures (Figure 1).

Atomic Structure

A crystal structure consists of a periodic pattern of atomic nuclei and a continuous (also periodic) distribution of electron density. As X-rays are scattered by electrons, it is possible to extract structure factors from the reflection intensities, and, by their Fourier transform, to calculate the electron density map, the peaks of which correspond to the centres of atoms. We can then approximate the structure by placing at these points isolated atoms of corresponding elements with ideal spherical symmetry. The positions (coordinates) of these atoms and their displacement parameters (see Atomic displacements below) can be refined by the least-squares technique so as to achieve the best agreement with the observed intensities. Usually, the structure determination ends at this stage. Atomic coordinates are referred to the coordinate axes parallel to the edges of the unit cell and published in fractional form, i.e. as x/a , y/b and z/c , where a , b and c are the unit cell parameters. All kinds of geometrical parameters of the molecule in a crystal can be calculated from these coordinates. Shortest vectors between centres of atoms give bond lengths and, of course, the atomic connectivity, i.e. the order in which the atoms are linked. Usually, the bond order (multiplicity) can be estimated roughly from a bond length in a straightforward way. Angles between bonds indicate the state of hybridization of a given atom. The conformation of a sterically flexible molecule can be described in terms of dihedral angles between planar fragments, or torsion angles. For ring systems, an unequivocal way of describing the conformation is provided by the ring puckering coordinates.

X-ray diffraction provided the first determination ever (in 1912) of the covalent bond length (C–C 1.544 Å in diamond) and is to the present day the overwhelming source of information on ‘molecular metrics’. The Cambridge Structural Database (CSD) is the world repository of small molecule crystal structures, which also comprises software for database access, structure visualisation and data analysis, and structural knowledge bases derived from the CSD (see the link from www.ccdc.cam.ac.uk). The CSD records bibliographic, chemical and crystallographic information for organic molecules and metal-organic compounds whose 3D structures have been determined using X-ray diffraction and neutron diffraction. The CSD stores results of single crystal

Figure 1 (a) Molecular structure of the hydroxyphenyl group in the crystal of 4-(methylamido)phenol, showing 50% displacement ellipsoids; maps of the deformation electron density (b) and Laplacian (c) in the same moiety (positive contours solid, negative dashed). studies and powder diffraction studies which yield 3D atomic coordinate data for at least all non-H atoms and from crystal structure data arising from publications in the open literature as well as private communications to the CSD (via direct data deposition). The number of organic and organometallic crystal structures, deposited at the CSD by January 2009, exceeds 460 000 (cf. 182 000 in 1998 and 67 000 in 1988). Of these, less than 1% were determined by neutron diffraction, all the rest by X-ray diffraction. All other spectroscopic methods that can give exact interatomic distances (gas-phase electron diffraction, microwave spectroscopy, etc.) yielded only hundreds of structure determinations. Furthermore, X-ray diffraction is unique among structural methods in that the number of experimental data (reflection intensities) exceeds the number of unknown variables (for each atom, three coordinates plus one isotropic or six anisotropic displacement parameters) by an order of magnitude. Currently, the reflections-to-variables ratio of 8 is regarded as the minimum acceptable for a good quality experiment. Therefore in determining the structural formula of a molecule and, to moderate precision, its geometry, the X-ray method needs no preconceived model of the structure, nor prior knowledge of the molecular symmetry. The number of possible reflections being proportional to the unit cell volume, and the latter to the molecular volume, this favourable situation persists up to molecules of considerable size (200 nonhydrogen atoms and even more).

This makes the X-ray method a very cost-effective tool for identification of newly synthesized compounds or newly isolated natural products: one needs a single crystal of ~ 0.01 mg to learn the composition and structural formula, usually without destroying the sample itself. In the past, solution of the phase problem was the major difficulty, the only available means (besides trial and error) being the Patterson method, effective only for structures containing at least one heavy atom. The advent of efficient direct methods of phase determination in the 1970s and the enhancement of these methods by phase relations of higher orders in the 1980s (which eliminated the problems for space groups without glide planes and screw axes) reduced the solution of a wholly unknown structure from art to near routine, if a crystal of good quality can be obtained.

A primary (but not unfallable) estimate of the quality of structure determination is a R-factor, showing the discrepancy between the experimentally observed structure factors of reflections (F_o) and those calculated from the determined structure (F_c), $R = \Sigma ||F_o| - |F_c|| / \Sigma |F_o|$. With modern precision of the data measurement, 'quality' structures have R of 0.02 to 0.06 (for observed reflections).

An R-factor based on F^2 (rather than F) became popular more recently, being more meaningful for weak reflections. For the same data, $R(F^2)$ is roughly twice the magnitude of $R(F)$.

Bond Distances and Their Precision

It was realized early on that bond lengths in molecular crystals depend mainly on the nature of the elements involved and on the bond order (the number of bonding electron pairs minus the number of antibonding ones), the crystal environment playing only a secondary role. Numerous tables and compendiums of bond lengths exist. **Tables 1** and **2** list some average ('standard') values, mainly from the comprehensive reviews by Kennard et al. based on the data from the CSD.

The measure of random errors in geometrical parameters, estimated standard deviations (esd), are routinely calculated in least-squares refinements. In good-quality studies of purely organic compounds, they may be as low as one or several thousandths of Å (for bonds not involving hydrogen atoms). Errors being in general in inverse

relation to the atomic number, in organometallic structures the esd of the heavy atom coordinates may be as small as 0.0001 Å, but those of the lighter ligand atoms can be of the order of 0.01 Å or more, so the latter define the esd of the metal–ligand *distances*. Differences in bond lengths, not exceeding 3 esd, are regarded as statistically insignificant. However, esd represent only the internal consistency of the data and say nothing of the various systematic errors inherent in the experiment (absorption, extinction, radiation decay of crystal, etc.), or of the model, which has the following limitations.

1. The X-ray diffraction method measures the distances between 'centres-of-gravity' of atoms' electron clouds, which need not necessarily coincide with the atomic nuclei. The difference is most pronounced for H (or D),

Figure 2 Ether group geometry determined by neutron (solid) and X-ray (dashed) diffraction; in the latter the O atom is shifted towards its lone-pair electrons.

its sole electron being shifted into the bond region; the X-ray estimates of $C(sp^2)-H$, $N-H$ and $O-H$ bond lengths are 0.93, 0.89 and 0.82 Å vs. 1.08, 1.01 and 0.97 Å determined by neutron diffraction in the same compounds. The effect is also considerable for sp -hybridized C and N atoms in acetylene and cyano groups.

2. Spherically symmetrical 'isolated' atoms model chemically bonded atoms, which are far from spherical. On refinement, atomic positions shift so as to compensate for the disregarded bonding electrons and/or lone pairs. Thus, a two-coordinate oxygen atom is shifted by 0.007–0.013 Å from its 'neutron' position (**Figure 2**) and C–O bond lengths are overestimated by 0.003–0.005 Å.
3. The X-ray method measures neither instantaneous nor time-average bond lengths, but the distances between mean atomic positions, averaged over all the crystal and all the duration of the experiment. This is much the biggest source of bias (see below).

Intermolecular Contacts

Distances between atoms not bonded directly to each other are rationalized in terms of the close packing model. An atom is regarded as a hard sphere of certain radius, van der Waals (vdW) radius, and a molecule as a superposition of such spheres. In a crystal, these bodies are closely packed but cannot dent each other. It is implied that a vdW radius is specific for a given element and remains the same in any contact, so that any $A...B$ contact distance equals the average of the $A...A$ and

Figure 3 A typical histogram of nonbonded contact distances; the half-height point A corresponds to the sum of the van der Waals radii (after Rowland and Taylor).

$B...B$ ones. Many systems of vdW radii have been developed. The pioneering one of Pauling (1939) used anion radii (which are close to the vdW radii) for the lack of direct data. The system of Bondi (1964), the most oft-quoted today, was based on experimental distances in a relatively small number of organic crystals and on some noncrystallographic data (gas kinetic collisions, critical densities, liquid properties).

However, because of the weakness and nonspecific nature of vdW forces, nonbonded distances vary more widely than bond lengths. By a statistical analysis of numerous structures, Rowland and Taylor derived a novel system of vdW radii (**Figure 3**, **Table 3**). Atoms of Cl, Br, I, S, Se and Te, forming one covalent bond, show a highly anisotropic shape in intermolecular contacts (**Figure 4**), which can be described as an ellipsoid compressed along the bond direction, while harder N, O and F atoms remain essentially spherical.

Nonbonded contacts considerably shorter than predicted by the vdW radii are often indicative of specific interactions between molecules (hydrogen bonds, secondary coordination, charge-transfer, etc.) and are useful in analysing solid-state properties (e.g. of organic conductors, so-called 'organic metals').

It must be stressed that vdW radii have different meanings in molecular mechanics, where the sum $R(A) + R(B)$ corresponds to the minimum of the potential curve of the *two-atom* $A...B$ interaction. Crystallographic vdW radii were derived to describe the distances of *closest* approach between *polyatomic* molecules, often of complex shapes, and are 8–20% shorter than the equilibrium radii. Only for inert gases, monoatomic in the solid state, do the two systems coincide.

Structural Databases

The abundant data on X-ray crystal structures was made easily accessible with the development of computerized

Table 3 Nonbonded contact (or van der Waals) radii for crystals (Å)

databases. Small-molecule organic and organometallic structures are covered by the Cambridge Structural Database (Cambridge, UK), which lists many compounds containing at least one 'organic' carbon (carbide, carbonate, CN or CO ligand carbon is not regarded as such). For each entry, the crystal lattice parameters and related data, atomic coordinates and (for more recent studies) ADP, bond distances and angles, molecular and structural formula are stored. The database is updated quarterly and widely distributed among academic and nonacademic users worldwide. Its software permits retrieval of entries according to the chemical class, full or partial compound name, composition and chemical connectivity, conditions of determination (pressure, temperature), as well as features of the three-dimensional structure. It also facilitates

various statistical and numerical tests on the retrieved data, in order to find regularities of structural parameters and correlations between them.

Other crystal structure databases exist, such as the Crystallography Open Database which currently (2009) includes some 80 000 small organic, inorganic and metal-organic structural entries. Crystal structures of minerals and other inorganic substances are also covered by the Inorganic Crystal Structure Database which is compiled by the University of Bonn (Germany, http://www.fiz-karlsruhe.de/icsd_content.html) and those of metals and alloys in CRYSTMET[®] (<http://www.tothcanada.com/>). Protein crystal structures are commonly recorded in the Protein Data Bank (<http://www.rcsb.org/pdb/>) and oligonucleotide structures in the Nucleic Acids Data Bank (<http://ndbserver.rutgers.edu/>).

Absolute Structure

Chiral molecules are those not superimposable with their mirror images, such as those containing a tetrahedral carbon (or other) atom with four different substituents (asymmetric centre). They are of great import in biochemistry: natural sugars, amino acids and hence proteins, etc. Molecules of the same chemical composition and molecular geometry, but differing by a mirror reflection (enantiomers, or optical isomers), are indistinguishable in their chemical behaviour (unless another chiral reagent is involved) and in most physical properties. Few physical methods can indicate the difference between enantiomers: optical rotation (ability to rotate the polarization plane of light, in the opposite sense for enantiomers), circular dichroism and the formation of crystals with chiral outer form. None, except X-ray diffraction, can determine the absolute configuration of an asymmetric atom, i.e. the real configuration of the substituents in space (*R* or *S*, see **Figure 5** for explanation). The notation introduced by Fischer was based on an arbitrary assignment of the absolute configuration of (+)-glyceraldehyde, to which other optically active compounds could be related by virtue of their chemical origin from one another.

Figure 5 Notation of the absolute configuration of an asymmetric carbon atom. The substituents are numbered according to certain rules (e.g. beginning with the highest atomic weights, e.g. $I > Br > Cl > F$); the highest-number substituent pointing away, the numbers of the three others increase clockwise for the *R* configuration and anti-clockwise for the *S* one.

For normal X-ray scattering, centrosymmetrically related reflections with indices hkl and $\bar{h}\bar{k}\bar{l}$ always have equal intensities (Friedel's law); thus the diffraction pattern is always centrosymmetric, no matter whether the crystal itself has an inversion centre or not. However, for wavelengths slightly lower than the absorption edge of an atom, a resonant interaction of the X-rays with the inner electrons results in *anomalous scattering*, in which both the intensity and the phase of the radiation are changed. The atomic scattering factor (f_a) becomes a complex function:

$$f_a = f + \Delta f' + i\Delta f'' \quad [1]$$

where $\Delta f'$ and $\Delta f''$ depend on the wavelength, and for a noncentrosymmetric crystal the hkl and $\bar{h}\bar{k}\bar{l}$ reflections differ in intensity. The effect is stronger for heavier atoms and longer wavelengths. Bijvoet (1951) first utilized this anomaly to determine the absolute configuration of the dextrorotatory (+)-tartaric acid in the form of its sodium-rubidium salt, using $ZrK\alpha$ radiation. (By good luck, this coincided with Fischer's notation.) Today, it is possible to determine reliably the absolute configuration of a medium-sized molecule containing one atom of phosphorus or a heavier element, using $MoK\alpha$ or $CuK\alpha$ X-radiation. With the latter wavelength, a careful routine experiment can determine an absolute configuration from the anomalous scattering of oxygen atoms as the heaviest element.

Various methods are used to determine the absolute configuration of the crystal structure, which necessarily defines that of a molecule (although a chiral crystal may consist of nonchiral molecules). The intensities of a few dozen reflections, for which the effect is the strongest, can be calculated together with their inversion equivalent (Friedel pairs) and compared to the observed intensities. Least-squares refinements of the 'solved' structure, and then of its inverted equivalent, will give a lower R-factor for the correct enantiomer. The anomalous scattering corrections themselves ($\Delta f''$) or some coefficients linked to them can be included in the least-squares refinement

as a variable. The best method is to refine the 'Flack' parameter during the least-squares procedure. This gives not only the absolute configuration of the crystal, but also (through the esd) a measure of the reliability of the assignment. In addition, it permits the identification and analysis of 'twins by inversion', a common problem faced by physicists trying to grow large enantiomerically pure crystals. Finally, if a structure contains more than one chiral centre, and one of them has a known absolute configuration, those of other(s) can always be determined, even if anomalous scattering is unobservable. For this purpose, an unknown chiral product can be cocrystallized with a known one and the structure of the complex solved by diffraction methods.

Atomic Displacements

Atoms and molecules in crystals are not static, but oscillate at their potential minima and in some cases can jump between different minima. At room temperature, nonhydrogen atoms in a well-ordered organic crystal perform thermal oscillations with mean square amplitudes $\langle u^2 \rangle$ of $0.04\text{--}0.05 \text{ \AA}^2$ (which means the r.m.s. amplitudes of $\sim 0.2 \text{ \AA}$, comparable with bond lengths). At 100 K (the practical limit for most cooling devices using liquid nitrogen) $\langle u^2 \rangle$ can be reduced to $\sim 0.015 \text{ \AA}^2$, but some (zero-point) oscillations persist even at 0 K. Generally, u is in inverse relation to the atomic mass; for outlying atoms of a molecule or some easily rotating substituents, it can be twice the average. Furthermore, atoms can be *disordered*, i.e. have different positions in different asymmetric units of the structure, which are presumed identical by definition of the symmetry of the crystal lattice. Both dynamic and static distortions of the lattice periodicity result in 'smearing' of the electron density, averaged in space over the entire crystal and in time over the entire duration of the experiment. The smearing is described by either atomic thermal parameters, or more precisely atomic displacement parameters (ADP), either in isotropic approximation (spherically averaged for each atom) or in anisotropic approximation, as a symmetrical third-order tensor with six independent parameters. Both representations imply harmonic oscillations; the real vibrations are always anharmonic to some extent, but it is really important to take this effect into account only in high-precision studies of electron density.

Visually, anisotropic ADPs are commonly presented as 'thermal ellipsoids' of a given probability, say, 50% (Figure 6). The atom's centre can be found inside the ellipsoid with this probability, and it has *equal* probability of reaching the ellipsoid in any direction. The principal axes of the ellipsoid are proportional to the components of $\langle u^2 \rangle$ in these directions, but other axes are not. The surface visualizing $\langle u^2 \rangle$ components in every direction is not an ellipsoid but a quadric surface of a 'peanut' shape (Figure 6b).

Figure 6 Atomic displacements in a metal–carbonyl moiety represented by thermal ellipsoids (a) and ‘peanut-shaped’ surfaces of $\langle u^2 \rangle^{1/2}$ (b).

Figure 7 In-phase vibrations (a) of a rigid group (CO, CN) and out-of-phase (b) of a flexible group (ethyl) can result in similar ADP ellipsoids.

Models of Molecular Vibrations

The coherent elastic (Bragg) scattering, which alone is measured in the normal X-ray diffraction study, can inform only about the average displacement of every single atom with respect to the crystal lattice. It carries no information whatsoever on how a displacement of one atom relates to that of another atom. In principle, such knowledge can be obtained from inelastic, or thermal diffuse scattering, but the latter is difficult both to measure (its peaks lying under the Bragg ones) and to interpret. Without this knowledge, the same ADPs can be interpreted in different ways, depending on whether the atoms oscillate in phase or out of phase (**Figure 7**).

However, vibrations of a molecular crystal are mainly external modes (oscillations of entire molecules). Intramolecular modes (except some torsional ones), which imply distorting a relatively rigid covalent-bond skeleton, contribute relatively little to the overall amplitudes. From this follows the rigid-bond criterion (Hirshfeld, 1975): if two atoms are linked by a covalent bond, their $\langle u^2 \rangle$ components along the bond direction must be almost equal. For accurately determined structures, this is true within 0.001 Å for X–X bonds (X=C, N, O), 0.003 Å for metal–ligand bonds and 0.005 Å for X–H or X–D bonds. The latter difference is in agreement with the $\langle u^2 \rangle$ of 0.006 Å, calculated from the C–H bond stretching frequency ν 2700–3300 cm^{−1}. Larger differences are indicative of molecular flexibility, as in crystalline Fe(III) complexes (spin-crossover effects), octahedral Cu(II) complexes (dynamic Jahn–Teller and pseudo-Jahn–

Figure 8 Systematic underestimation of the length of a librating A–B bond. The terminal atom moves along the AA' arc; its average position $\bar{A}$ is found as the centre-of-gravity of the smeared electron density (hatched) and lies within the arc.

Teller distortions) and binuclear Mn(II)–Mn(IV) complexes (valence disorder).

In an ideally rigid molecule, the same criterion applies to *all* interatomic vectors. The TLS model, introduced by Schomaker and Trueblood (1968), describes the motion of such a molecule with three tensors, representing respectively: translations along three principal axes, librations around these axes and screw motions (for noncentrosymmetric cases only). Subtracting the ADPs predicted by this model, from the actual ones, internal nonrigidity of the molecule can be revealed. Torsional motions of a (presumed rigid) group within a molecule can be analysed in the same way, determining torsional amplitudes and, from them, force constants and barriers to internal motion.

Correcting Bond Lengths

Rigidly bonded atoms usually perform oscillations along arcs (librations). The electron density thus smeared has its centre-of-gravity (taken for the average atomic position) inside the arc. Hence the X-ray method tends to underestimate bond lengths systematically, the more so (up to 0.03 Å) at higher temperatures (while the real bonds slightly lengthen with temperature). The libration of a C–C bond (~ 1.5 Å) by 5–6 Å results in a spurious shortening of 0.005 Å, and when by 10 Å, in a shortening of 0.025 Å (**Figure 8**).

If the ADPs from a standard least-squares are consistent with the rigid-body model, bond lengths can be corrected for the spurious shortening. Thus, in a nonrigid molecule of *o*-terphenyl, the mean C–C distance in the phenyl ring is 1.389 Å before correction and 1.398 Å after it, as compared with the $r_g = 1.399 \pm 0.002$ Å from gas-phase electron diffraction. Nevertheless, any thermal motion correction is based on some preconceived idea about the nature of the motion and demands caution. The rigid-bond test can disprove molecular rigidity but not always prove it, as the atoms may vibrate along their connecting vector with the same $\langle u^2 \rangle$, but quite out of phase. The best way to reduce these errors is to diminish the vibrations themselves by cooling the crystal.

Disorder

From a diffraction study at one temperature one cannot distinguish between dynamic (thermal motion) and static (disorder) displacements. However, if cooling fails to reduce the ADPs, the latter are certainly of static nature, as in the case of ferrocene. The early X-ray studies at room temperature (1951–1956) of the monoclinic modification proved the molecule to possess the crystallographic C_i symmetry, implying the staggered conformation of the rings, in contrast with the eclipsed one in the gas phase. The persistence of a large ADP at 173 K could only be explained as a static disorder, for which various models were suggested. At 164 K, a phase transition occurred into an ordered triclinic structure with four symmetrically independent molecules, all of which adopted nearly (within 10°) eclipsed conformations. A statistical averaging of these molecular orientations results in a picture similar to that observed in the disordered phase. Thus the centrosymmetric conformation is likely to be spurious.

Erratic ADP

In a least-squares refinement, ADPs tend to become ultimate ‘sinks’ of all unaccounted for systematic errors, particularly absorption, anisotropic extinction, sometimes incorrect assignment of atomic type or nonstoichiometric occupancy of the position. Erratically elongated ADP ellipsoids, uncorrelated, with those of adjacent atoms, usually betray gross blunders in structure solution, e.g. incorrect crystallographic symmetry or lattice parameters.

Electron Density

The second level of a crystal structure investigation is to go beyond the independent atom model and to resolve more subtle details of the electron density distribution. For such a study one needs to measure by an order of magnitude more experimental data (measuring all

symmetrically equivalents of each reflection rather than just one, increasing the maximum 2θ angle) and to address carefully all possible sources of systematic errors, which can be irrelevant on the atomic approximation level. The mathematical formalisms and software for such studies are still evolving. A limited number of electron density studies have been published and of these a substantial proportion were with the multipole technique (see below).

Deformation Maps

The earliest approach was to calculate the total electron density map by a Fourier synthesis and to subtract from its density of isolated atoms, centred at atomic nuclei positions (*promolecule*). These nuclei positions were either determined directly by a neutron diffraction experiment (X–N method) or calculated using only high-order X-ray reflections (X–X_{ho} method), making use of the fact that valence electrons scatter X-rays mainly at lower angles, while the inner electron shells remain practically unperturbed by chemical bonding. The resulting *deformation electron density* maps showed some well-expected features: peaks of electron density in the areas of covalent bonds and lone electron pairs, outward shift of bonding peaks in a cyclopropane ring (‘bond bending’, **Figure 9**) and so on. However, no peaks appear on bonds involving atoms with the valence shells more than half-filled, e.g. fluorine. In organometallic complexes, only insignificant peaks of electron density were found on the formally quadruple Cr–Cr bond in chromium acetate (0.1 eÅ^{-3}) and the single Mn–Mn bond in $\text{Mn}_2(\text{CO})_{10}$ (0.05 eÅ^{-3}), and none at all on the Fe–Fe bond in $[(\text{C}_5\text{H}_5)\text{Fe}(\text{CO})_2]_2$. This reveals the inadequacy of the spherically averaged independent atom

Figure 9 Deformation electron density map in a cyclopropane ring confirms the concept of ‘bent bonds’ (dashed lines).

as the reference: the $(1s)^2(2s)^2(2p)^5$ atom F has an average of $5/3$ and electrons on each p-orbital, which are subtracted from the bonding density. While in fact this atom contributes only one electron for bond formation, the excessive subtraction of $2/3 e$ more than outweighs the accumulation of electrons in the bond area.

More informative deformation maps could be obtained by subtracting a correctly preoriented independent atom, or a reference atom in a corresponding state of hybridization. Features of one particular bond in a molecule can be most highlighted by subtracting the (calculated by MO methods) electron densities of the two fragments, differing from the molecule by the absence of only this bond.

More information can be extracted by topological analysis of the electron density map, particularly using the Laplacian (second gradient) of the electron density:

$$\nabla^2 \rho(\mathbf{r}) = \partial^2 \rho(\mathbf{r}) / \partial x^2 + \partial^2 \rho(\mathbf{r}) / \partial y^2 + \partial^2 \rho(\mathbf{r}) / \partial z^2$$

which has maxima in the areas where electron density accumulates (i.e. on chemical bonds) and minima where it depletes.

Determining the phases of structure factors (especially for noncentrosymmetric structures) with the precision sufficient for a deformation density map is an extremely difficult task, as is combining X-ray and neutron data in a sensible way. The irrelevance of the valence electron density for high-order X-ray scattering is also only an approximation (it is correct for the spherically symmetric case only).

Multipole Analysis

More promising is to describe the deformation electron density by a series of spherical harmonic density functions (multipoles), which can be included into least-squares refinement. The inner (core) electron shells of an atom are presumed and the κ parameter, which describes the isotropic expansion ($\kappa < 1$) or contraction ($\kappa > 1$) of the valence shell as a whole. Multipole parameters of higher orders describe deviations of the electron density from spherical symmetry. They can be related to the products of atomic orbitals: monopolar to ss, dipolar to sp, quadrupolar to pp, octopolar to 2p3d and hexadecapolar to 3d3d, and used to analyse atomic orbital populations more directly than density maps.

Studies of octahedral complexes $M(\text{NH}_3)_6^{3+}$, $M(\text{CN})_6^{3-}$ ($M = \text{Cr}, \text{Co}$) and $\text{Cr}(\text{CO})_6$ have confirmed the predictions of the ligand field theory: 66 to 77% of 3d electrons occupy the t_{2g} orbitals (field-stabilized) to the depletion of the destabilized e_g orbitals.

Attempts have been made to develop a set of deformation parameters, transferable between chemically similar molecules. Their application is much less time-consuming than a full electron density study and may

give more realistic least-squares refinement (reduction of displacement parameters) and better predictions of molecular properties than the atomic approximation.

All methods of electron density analysis are hindered by the difficulty of distinguishing between the real (static) deformation and smearing due to thermal motion.

Estimates of Electric Properties

It is possible to estimate directly the charges on atoms and groups of atoms in a crystal, by integrating the electron density over the corresponding areas, if physically sensible borders for them can be suggested. For a monatomic ion, the dependence of the integral electron density inside a sphere centred on this atom as the function of the radius of this sphere has a distinct minimum, indicating the 'ion boundary'. For the anion in NH_4Cl , this gives the radius of 1.75 Å with 17.5 e inside the sphere, showing an incomplete charge transfer. In $\text{TTF} \cdot \text{TCNQ}$, an organic complex with metallic conductivity, integration over parallelepiped-shaped boxes gave the degree of charge transfer of $\sim 0.6 e$ from TTF to TCNQ, in agreement with other estimates. In more complex cases, the physical boundary of an ion can be determined as the surface of zero flux, on which the electron density gradient vanishes.

The electrostatic potential (energy needed to bring a unit positive charge from infinity to a given point) and its first and second derivatives (electric field and its gradient) are of great importance in understanding intermolecular interactions, molecular recognition and reaction mechanisms (as they define the path by which the reagent approaches the substrate). The electrostatic potential can be calculated from the experimental electron density or directly or indirectly from a high-precision set of structure factors.

Small Molecule X-Ray Crystallography, Theory and Workflow

Delphine D Le Pevelen, Chiralabs Limited, Oxfordshire, UK

CCD charge coupled device

Small molecule X-ray diffraction is the most widely used technique for obtaining full three-dimensional structural information of crystalline materials. It reveals the molecular packing, the molecular conformation, the molecular configuration, and the presence or absence of guest molecules and gives an insight into the nature of intra- and intermolecular interactions and disorder (either static or dynamic). It is applied in many scientific fields ranging from mineralogy, metallurgy, materials science, and food industry to pharmaceutical industry. As technology improves and, in particular, X-ray diffraction instruments (diffractometers) become more and more user friendly, the theory underlying this subject tends to be overlooked. This article presents the basis of X-ray diffraction theory and describes a typical workflow in small molecule crystal structure determination.

Diffraction Theory

The interaction of X-rays with matter results mainly in two processes: absorption phenomena and scattering. In the former, incident photons are absorbed by the atoms of the matter and increase its energy and, inter alia, temperature. The photon energy can sometimes result in the ejection of inner-shell electrons of the target, leaving it in an ionized state; this is the so-called photoelectric effect.

The ionized atom can return to its nonexcited state with the emission of an X-ray photon, the wavelength of which is characteristic of this specific atom (fluorescence X) (Figure 1).

For the scattering process, two subtypes can be observed. If the incident photons are scattered without a loss of energy and therefore possess the same wavelength, the scattering is known as coherent scattering or Thomson scattering. On the contrary, if the incident photons are scattered with a loss of energy, that is, possess a longer wavelength after the interaction with the matter, the scattering is incoherent; this is most usually known as Compton scattering. X-ray diffraction is based on coherent scattering, the Compton scattering contributing only to the overall background in the data.

Scattering by an Electron

An electron in the path of the incident X-ray beam vibrates at the same frequency as that of the incoming beam. It thus becomes a secondary source of X-rays of the same energy as the incident beam. The intensity of the scattered X-rays in a particular direction is given by the Thomson equation:

$$I = I_0 \frac{e^4}{m^2 r^2 c^4} \frac{1 + \cos^2 2\theta}{2} \quad [1]$$

where I_0 is the intensity of the incident beam, e the charge on the electron, m the mass of the electron, r the distance between the scattering electron and the detector, c the speed of the light, and 2θ is the angle between the incident beam and the direction of observation.

Figure 1 Schematic representation of the interaction between X-rays and matter.

The term:

$$P = \frac{1 + \cos^2 2\theta}{2} \quad [2]$$

is called the polarization factor. It indicates that the scattered radiation is maximum in the direction of the nonpolarized incident beam and minimum in the direction perpendicular to it.

Scattering by Two Electrons

As discussed in the previous section, each electron in the path of the incident X-ray beam becomes a secondary source of X-rays of the same energy as the incident beam. All these scattered X-rays will interfere and create some interference pattern. All the interferences will not necessarily be constructive; some will be destructive.

In **Figure 2**, let us suppose that two scattering centers (two electrons) are located at M and M' positions. The unit vector associated with the direction of propagation of the incident X-ray beam is $\mathbf{u}_0$ and the wave vector $\mathbf{s}_0$ is defined by:

$$\mathbf{s}_0 = \frac{1}{\lambda} \mathbf{u}_0 \quad [3]$$

The path difference between the wave scattered by M and that scattered by M' in the direction defined by the unit vector $\mathbf{u}_1$ is as follows:

$$\delta = MK - HM = r(\mathbf{u}_1 - \mathbf{u}_0) \quad [4]$$

This can be written regarding eqn [3] as follows:

$$\delta = r\lambda(\mathbf{s}_1 - \mathbf{s}_0) \quad [5]$$

$\mathbf{S}$ defined as

$$\mathbf{S} = \mathbf{s}_1 - \mathbf{s}_0 \quad [6]$$

is the scattering vector for the direction of propagation.

The modulus of $\mathbf{S}$ can be easily derived from **Figure 2**:

$$|\mathbf{S}| = \frac{2 \sin \theta}{\lambda} \quad [7]$$

The phase difference between the wave scattered by M and that scattered by M' in the direction defined by the unit vector $\mathbf{u}_1$ is therefore:

$$\varphi = 2\pi \mathbf{S} \mathbf{r} \quad [8]$$

If two planes are considered normal to $\mathbf{S}$ passing through M and M' (for clarity, only a plane passing through M has been plotted in **Figure 2**), the interference can be expressed as a result of specular reflection with these planes.

If A_M is the amplitude of the wave scattered by M, the amplitude of the wave scattered by M' will be described as:

$$A_M \exp(2\pi \mathbf{S} \mathbf{r}) \quad [9]$$

This forms the basis for extending the formulism to many electrons.

Scattering by More Electrons

If now there are N point scatterers along the path of the incident wave, the resulting amplitude scattered is:

$$F(\mathbf{S}) = \sum_{j=1}^N A_j \exp(i 2\pi \mathbf{S} \mathbf{r}_j) \quad [10]$$

Figure 2 Interference of scattered waves. The scattering centers are at M and M'; $\mathbf{u}_0$ and $\mathbf{u}_1$ are unit vectors and $\mathbf{S}$ is the scattering vector.

where A_j is the amplitude of the wave scattered by the j th scatterer.

If the scattering centers form a continuum, and thus correspond to an element of volume dr , this volume will contain $\rho(r)dr$ electrons. The wave scattered on this volume is described by:

$$\rho(r)dr \exp(i 2\pi \mathbf{S}r) \quad [11]$$

The total amplitude of the scattered wave will be:

$$F(\mathbf{S}) = \int_v \rho(r) \exp(i 2\pi \mathbf{S}r) dr \quad [12]$$

This latter equation is an important result in diffraction theory. It means that the amplitude of the scattered wave is the Fourier transform of the electron density.

Hence as a corollary, the electronic density is the inverse Fourier transform of the amplitudes of the scattered waves.

Scattering by Atoms

The amplitude of the scattered wave by an atom is the Fourier transform of the density $\rho_a(r)$. It is also called the atomic scattering factor and is denoted f_a . The ρ_a and so f_a are well known for atoms and ions of most of the elements and are obtained from quantum mechanical calculations (Hartree–Fock methods for light atoms; Thomas–Fermi approximations for heavier ones). The reader can easily find them in standard reference tables, and they are also incorporated into crystallographic software.

Figure 3 shows a typical variation of the atomic scattering factor with the value of $\sin \theta/\lambda$ for two types of atoms (carbon and oxygen). The curves reach a maximum value at $\sin \theta/\lambda = 0$. This value corresponds to the atomic number Z of the atom considered. The curve then decreases continuously with increasing $\sin \theta/\lambda$. At high

values of $\sin \theta/\lambda$, most of the radiation scattered is due to the core electrons in contrary to the valence electrons contributing more at low $\sin \theta/\lambda$ values.

However, in a crystal, the atoms are not stationary; they possess some thermal vibrations. As a consequence, the electron density of the atoms is more diffuse and therefore the scattering process is affected. To take into account this effect, in the case of an isotropic thermal motion, the atomic scattering factor has to be multiplied by a term containing an atomic temperature factor B (Debye–Waller temperature factor) expressed in $\text{\AA}^2$.

$$f_{at} = f_a \exp(-B \sin^2 \theta/\lambda^2) \quad [13]$$

B is defined as:

$$B = 8\pi^2 U \quad [14]$$

where U is the square mean shift of the atom with respect to the position of equilibrium, also called the isotropic displacement parameter.

The new adjusted atomic scattering factor together with the previous one is plotted in **Figure 4**. It can be seen that the principal effect of the introduction of the thermal parameter on the atomic scattering factor is to reduce the capacity for scattering with increasing values of $\sin \theta/\lambda$.

Thus, by performing some diffraction experiments at a temperature lower than ambient, the thermal motion will be reduced and the intensities of reflections enhanced.

Another phenomenon may affect the capacity of scattering: anomalous scattering. It occurs when the incident X-ray energy is sufficient to cause a photoelectric effect and fluorescence X as described in the Diffraction Theory section. The produced X-rays are out of phase with the incident beam. The atomic scattering factor becomes:

$$f = f_a + \Delta f' + if'' \quad [15]$$

Figure 3 Illustrative scattering factors for C and O atoms without taking into account thermal vibrations.

Figure 4 Effect of thermal vibrations on scattering factors for C and O atoms.

$\Delta f'$ and f'' are respectively called the real and imaginary dispersion corrections. $\Delta f'$ is negative; it decreases the effective number of scattering electrons. The imaginary part f'' is positive and corresponds to a scattered wave exactly $\pi/2$ out of phase with the incident beam.

Calculated values of $\Delta f'$ and f'' for atomic elements at common used wavelengths (e.g., $\lambda = 1.5418$ and $0.7107 \text{ \AA}$) can be found in the standard reference tables and are also incorporated into crystallographic software.

Anomalous scattering is negligible for light atoms such as carbon, nitrogen, and oxygen. It should, however, be considered for atoms with higher Z number for conventional X-ray sources.

Scattering by a Unit Cell

The amplitude of the scattered wave by a unit cell containing N atoms is:

$$F_{\text{uc}}(\mathbf{S}) = \sum_{j=1}^N f_j \exp i 2\pi \mathbf{S} \mathbf{r}_j \quad [16]$$

where f_j is the atomic scattering factor of the j th atom and $\mathbf{r}_j$ its position.

This relation is also valid for the amplitude scattered by an N atom molecule.

Diffraction by a Crystal

The electron density for an entire crystal is the product of convolution of the electronic density in the unit cell with a lattice function representing an infinite three-dimensional lattice:

$$\rho_{\infty}(\mathbf{r}) = \rho_{\text{uc}}(\mathbf{r})L(\mathbf{r}) \quad [17]$$

with

$$L(\mathbf{r}) = \sum_{u,v,w=-\infty}^{+\infty} \delta(\mathbf{r} - \mathbf{r}_{u,v,w}) \quad [18]$$

where $\mathbf{r}_{u,v,w} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c}$, u , v , and w being integer values.

$L(\mathbf{r})$ is 0 except when $\mathbf{r} = \mathbf{r}_{u,v,w}$

The amplitude of the scattered wave by the entire crystal is the Fourier transform of $\rho_{\infty}(\mathbf{r})$:

$$\begin{aligned} F_{\infty}(\mathbf{S}) &= FT[\rho_{\text{uc}}(\mathbf{r})] FT[L(\mathbf{r})] \\ &= F_{\text{uc}}(\mathbf{S}) \frac{1}{V} \sum_{b,k,l=-\infty}^{+\infty} \delta(\mathbf{S} - \mathbf{r}_r) \\ &= \frac{1}{V} F_{\text{uc}}(bkl) \sum_{b,k,l=-\infty}^{+\infty} \delta(\mathbf{S} - \mathbf{r}_r) \end{aligned} \quad [19]$$

where $\mathbf{r}_r = b\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$.

For a finite crystal, this equation becomes:

$$\begin{aligned} F(\mathbf{S}) &= \frac{1}{V} F_{\text{uc}}(bkl) \sum_{b,k,l=-\infty}^{+\infty} \delta(\mathbf{S} - \mathbf{r}_r) D(\mathbf{S}) \\ &= \frac{1}{V} F_{\text{uc}}(bkl) \sum_{b,k,l=-\infty}^{+\infty} D(\mathbf{S} - \mathbf{r}_r) \end{aligned} \quad [20]$$

where $D(\mathbf{S}) = \int_V \exp(i 2\pi \mathbf{S} \mathbf{r}) d\mathbf{r}$.

Here $\mathbf{r}_r$ is a lattice vector belonging to a particular space, called the reciprocal space. The notion of reciprocal space was created by P. Edwald in order to better represent mathematically an X-ray diffraction pattern. It can be regarded as the Fourier transform of the crystal lattice.

The reciprocal lattice is defined by the three vectors $\mathbf{a}^*$, $\mathbf{b}^*$, and $\mathbf{c}^*$ and is related to the direct lattice by the following equations:

$$\mathbf{a}^* = \frac{\mathbf{b} \times \mathbf{c}}{[\mathbf{a}(\mathbf{b} \times \mathbf{c})]} = \frac{\mathbf{b} \times \mathbf{c}}{V} \quad [21]$$

$$\mathbf{b}^* = \frac{\mathbf{c} \times \mathbf{a}}{[\mathbf{a}(\mathbf{b} \times \mathbf{c})]} = \frac{\mathbf{c} \times \mathbf{a}}{V} \quad [22]$$

$$\mathbf{c}^* = \frac{\mathbf{a} \times \mathbf{b}}{[\mathbf{a}(\mathbf{b} \times \mathbf{c})]} = \frac{\mathbf{a} \times \mathbf{b}}{V} \quad [23]$$

These relations, in terms of moduli, become:

$$a^* = \frac{bc \sin \alpha}{V} \quad [24]$$

$$b^* = \frac{ca \sin \beta}{V} \quad [25]$$

$$c^* = \frac{ab \sin \gamma}{V} \quad [26]$$

The vectors of the reciprocal lattice $\mathbf{a}^*$, $\mathbf{b}^*$, and $\mathbf{c}^*$ also obey the following relationships:

$$\mathbf{a}^* \mathbf{a} = \mathbf{b}^* \mathbf{b} = \mathbf{c}^* \mathbf{c} = 1 \quad [27]$$

$$\mathbf{a}^* \mathbf{b} = \mathbf{a}^* \mathbf{c} = \mathbf{b}^* \mathbf{a} = \mathbf{b}^* \mathbf{c} = \mathbf{c}^* \mathbf{a} = \mathbf{c}^* \mathbf{b} = 0 \quad [28]$$

The last relation indicates that $\mathbf{a}^*$ is normal to the plane ($\mathbf{b}, \mathbf{c}$), $\mathbf{b}^*$ is normal to the plane ($\mathbf{a}, \mathbf{c}$), and $\mathbf{c}^*$ is normal to the plane ($\mathbf{a}, \mathbf{b}$).

Another interesting property of the reciprocal space is that:

$$\mathbf{r}_r = \frac{1}{d_{hkl}} \quad [29]$$

where d_{hkl} is the spacing of the planes (hkl) in the direct lattice.

Following eqns [19] and [20], it can be seen that for a crystal (periodic object), the amplitude of the scattered wave will be different from 0 only if $\mathbf{S}$ coincides with a reciprocal lattice point, $\mathbf{S} = \mathbf{r}_r$.

The amplitude is then simply associated to the determination of the amplitude from the unit cell $F_{uc}(hkl)$, called the structure factor.

$$F_{uc}(hkl) = F(hkl) = \sum_{j=1}^N f_j \exp i 2\pi \mathbf{S} \mathbf{r}_j \quad [30]$$

with

$$\mathbf{S} = \mathbf{r}_r \quad [31]$$

By posing $\mathbf{S}$ and $\mathbf{r}$ respectively as:

$$\mathbf{S} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$$

$$\mathbf{r} = x\mathbf{a} + y\mathbf{b} + z\mathbf{c}$$

and by using eqns [27] and [28],

$$\mathbf{S} \mathbf{r} = (h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*)(x\mathbf{a} + y\mathbf{b} + z\mathbf{c}) = hx + ky + lz$$

As a result eqn [30] can now be written as:

$$F(hkl) = \sum_{j=1}^N f_j \exp i 2\pi (hx_j + ky_j + lz_j) \quad [32]$$

When taking in account the effect of thermal agitation, this relation becomes:

$$F(hkl) = \sum_{j=1}^N f_{aj} \exp(-8\pi^2 U_j \sin^2 \theta / \lambda^2) \times \exp 2\pi i (hx_j + ky_j + lz_j) \quad [33]$$

As a corollary, the electron density is expressed as:

$$\rho(xyz) = \frac{1}{V} \sum_{b,k,l=-\infty}^{+\infty} F(hkl) \exp -i 2\pi (bx + ky + lz) \quad [34]$$

It is interesting to point out that when looking at eqn [32] it is clear that a structure factor is complex. It can be therefore written as:

$$F(hkl) = \sum_{j=1}^N f_j \cos 2\pi (hx_j + ky_j + lz_j) + i \sum_{j=1}^N f_j \sin 2\pi (hx_j + ky_j + lz_j) = A_{hkl} + iB_{hkl} \quad [35]$$

Another notation of writing this complex number is:

$$F(hkl) = |F(hkl)| \exp(i\varphi_{hkl}) \quad [36]$$

where φ is the phase of the structure factor (**Figure 5**) and is defined as:

$$\varphi_{hkl} = \arctan(B_{hkl}/A_{hkl}) \quad [37]$$

Bragg's Law

Bragg's law gives the simple condition under which a diffracted beam can be observed. **Figure 6** shows a beam of parallel X-rays penetrating a set of parallel lattice planes with indices h,k,l of spacing d and at an angle of incidence θ . The lattice planes are represented behaving as a mirror.

The path difference between the waves scattered in A and B is equal to:

$$IB + BJ = 2d \sin \theta \quad [38]$$

Figure 5 As a complex number, F_{hkl} possesses a real part A and an imaginary part B ($F_{hkl} = A + iB$). It may also be defined by its modulus $|F_{hkl}|$ and its phase angle φ .

Figure 6 The condition for reflection – the Bragg's law.

The 'reflected' waves will combine to form a diffracted beam (maximum constructive interference, commonly called 'reflection') if the path difference is a multiple of the wavelength λ :

$$2d_{hkl} \sin \theta = n\lambda \quad [39]$$

Equation [39] is the Bragg's equation. 'Reflected' waves that do not obey this rule will interfere destructively. In eqn [39], the value n gives the 'order' of the diffraction.

An effect of diffraction of n th order due to a reflection from lattice planes (hkl) can always be interpreted as a reflection of first order from the imaginary lattice planes ($h'k'l'$) with indices $h' = nb$, $k' = nk$, and $l' = nl$ and a spacing $d_{h'k'l'} = d_{hkl}/n$ ($n = 2$ for (hkl) planes is equivalent to $n = 1$ for ($2h2k2l$) planes with $d/2$ spacing).

In practice, the value of n can therefore be considered to be 1 and eqn [39] becomes:

$$2d_{hkl} \sin \theta = \lambda \quad [40]$$

The reader can notice the equivalence of Bragg's law with eqn [31]:

$$S = r_r$$

Using eqns [7] and [29], eqn [31] can be written as:

$$S = \frac{2 \sin \theta}{\lambda} = \frac{1}{d_{hkl}}$$

From eqn [40], the minimum value of d (also referred to as resolution) can be determined for any common radiation. It will correspond to the maximum value of θ of the diffraction data. As an example, for Mo $K\alpha$ radiation ($0.71 \text{ \AA}$), $d_{\min}$ will be $0.71/2 \sin 27^\circ = 0.78 \text{ \AA}$.

The value $\theta_{\max}$ should provide the minimum number of reflections recommended for an average structural study to be measured. In practice, this value could be set to 27° for Mo $K\alpha$ radiation (in 2007, the guideline from *Acta Crystallographica* Section E set $\theta_{\max} > 25^\circ$ for Mo $K\alpha$, and $\theta_{\max} > 67^\circ$ for Cu $K\alpha$).

Intensities and the Phase Problem

Experimentally, from the diffraction pattern, only the intensities $I(bkl)$ are obtained. These integrated intensities are given by:

$$I(bkl) = I_0 \frac{e^4}{(m^2 c^4)} \frac{\lambda^3 V_c}{V_{uc}^2} LPTE |F(bkl)|^2 \quad [41]$$

where I_0 is the intensity of the incident beam, λ the wavelength, V_c the volume of the crystal, V_{uc} the volume of the unit cell, L the Lorentz factor (during the measure of the intensity from a moving crystal, this factor takes into account the length of time the crystal remains in the diffracting position; it depends on the diffraction geometry and the Bragg angle), P the polarization factor defined in the Thomson equation, T a transmission factor (it depends on the capacity of the crystal to absorb the X-rays), and E is the extinction coefficient (it depends on the mosaic structure of the crystal). The reader is encouraged to read further literature to have more information on each of these factors.

The important point to make regarding eqn [41] is that the intensities are proportional to the square of the structure factor amplitude:

$$I(bkl) \propto |F(bkl)|^2 \quad [42]$$

It can be seen that no information about the phase of the structure factor is available directly from the intensities. Therefore, the calculation of the electron density cannot be performed directly from experimental measurements. This particular problem is called the phase problem. Methods to overcome it will be described in the sections related to the crystal structure determination.

Particular Intensity Calculations

Calculation of the Intensity of a Reflection

– $h - k - l$: $I(\bar{h}\bar{k}\bar{l})$

In what follows, it is supposed that f_j is real and that there is no anomalous scattering. In accordance with eqn [35],

$$F(bkl) = A_{bkl} + iB_{bkl}$$

$$\begin{aligned} F(\bar{b}\bar{k}\bar{l}) &= \sum_{j=1}^N f_j \cos 2\pi(-bx_j - ky_j - lz_j) \\ &+ i \sum_{j=1}^N f_j \sin 2\pi(-bx_j - ky_j - lz_j) = A_{bkl} - iB_{bkl} \end{aligned}$$

As a result, using eqn [42], the corresponding intensities can be deduced:

$$I(bkl) \propto A_{bkl}^2 + B_{bkl}^2$$

$$I(\bar{b}\bar{k}\bar{l}) \propto A_{bkl}^2 + B_{bkl}^2$$

So

$$I(bkl) = I(\bar{b}\bar{k}\bar{l}) \text{ or } |F(bkl)| = |F(\bar{b}\bar{k}\bar{l})| \quad [43]$$

The intensity of a reflection $-h - k - l$ is equal to the intensity of the corresponding reflection hkl . The relation described in eqn [43] is called Friedel's law.

It can also be proven that as a consequence,

$$\varphi_{\bar{b}\bar{k}\bar{l}} = -\varphi_{bkl} \quad [44]$$

In the case of anomalous scattering (f_j follows a relation of the type described in eqn [15]), Friedel's law is not generally satisfied anymore; the only occasions where it is the case are when the structure or reflections are centrosymmetric or the crystal is composed solely of a single anomalous scatterer.

Calculation of the Intensity for a Centrosymmetric Structure

In what follows, it is supposed that f_j is real. Let us suppose the existence of an inversion center on the origin. For each atom located on (x, y, z) , there will be an atom located on $(-x, -y, -z)$. So the total number of atoms N can be divided into two subgroups $N/2$. The

structure factor is:

$$\begin{aligned} F(bkl) &= \sum_{j=1}^{N/2} f_j \cos 2\pi(bx_j + ky_j + lz_j) \\ &+ i \sum_{j=1}^{N/2} f_j \sin 2\pi(bx_j + ky_j + lz_j) \\ &+ \sum_{j=1}^{N/2} f_j \cos 2\pi(-bx_j - ky_j - lz_j) \\ &+ i \sum_{j=1}^{N/2} f_j \sin 2\pi(-bx_j - ky_j - lz_j) \quad [45] \end{aligned}$$

$$F(bkl) = 2 \sum_{j=1}^{N/2} f_j \cos 2\pi(bx_j + ky_j + lz_j)$$

For a centrosymmetric structure, $F(bkl)$ is therefore real and the phase φ of the structure factor can be only either 0° or 180° . If $F(bkl) = A_{bkl}$, the intensity is:

$$I(bkl) = A_{bkl}^2 \quad [46]$$

Electron Density

Earlier in this article (in the section 'Diffraction by a Crystal'), it has been seen with eqn [34] that the electron density can be expressed as:

$$\rho(xyz) = \frac{1}{V} \sum_{b,k,l=-\infty}^{+\infty} F(bkl) \exp -i2\pi(bx + ky + lz)$$

If in this expression, the contribution of $F(bkl)$ is distinguished from that of $F(\bar{b}\bar{k}\bar{l})$, this expression becomes:

$$\begin{aligned} \rho(xyz) &= \frac{1}{V} \sum_{b=0}^{+\infty} \sum_{k=-\infty}^{+\infty} \sum_{l=-\infty}^{+\infty} \{ |F(bkl)| \exp -i2\pi(bx + ky + lz) \\ &\times \exp i\varphi(bkl) + |F(\bar{b}\bar{k}\bar{l})| \exp -i2\pi(-bx - ky - lz) \\ &\times \exp i\varphi(\bar{b}\bar{k}\bar{l}) \} \end{aligned}$$

By using eqns [43] and [44], and the polar form of the complex number, it can be written as:

$$\begin{aligned} &\frac{1}{V} \sum_{b=0}^{+\infty} \sum_{k=-\infty}^{+\infty} \sum_{l=-\infty}^{+\infty} |F(bkl)| \{ [\cos 2\pi(bx + ky + lz) \\ &- i \sin 2\pi(bx + ky + lz)] \cdot [\cos \varphi(bkl) \\ &+ i \sin \varphi(bkl)] + \cos 2\pi(-bx - ky - lz) \\ &+ i \sin 2\pi(-bx - ky - lz)] [\cos \varphi(\bar{b}\bar{k}\bar{l}) - i \sin \varphi(\bar{b}\bar{k}\bar{l})] \} \\ &= \frac{2}{V} \sum_{b=0}^{+\infty} \sum_{k=-\infty}^{+\infty} \sum_{l=-\infty}^{+\infty} |F(bkl)| [\cos 2\pi(bx + ky + lz) \cos \varphi(bkl) \\ &+ \sin 2\pi(bx + ky + lz) \sin \varphi(bkl)] \end{aligned}$$

This can be written using common trigonometric relationships as:

$$\rho(xyz) = \frac{2}{V} \sum_{h=0}^{+\infty} \sum_{k=-\infty}^{+\infty} \sum_{l=-\infty}^{+\infty} |F(hkl)| \cos[2\pi(bx + ky + lz) - \varphi(hkl)] \quad [47]$$

Crystal Symmetry

A crystal is formed by a regular repeat (translational repeat) in the three-dimensional space of an entity called the unit cell. The unit cell is the smallest volume (parallelepiped) that can be built in order to best represent the crystal. It contains the atoms from one or more molecules that can be related by symmetry operations (note, however, that molecules can span the borders of a unit cell, and thus the atoms within a single unit cell may not be a contiguous molecule). Moreover, each of the repeats can be represented as a point, and all the points will form a lattice.

The unit cell is defined by three vectors **a**, **b**, and **c** (Figure 7). The length of these vectors and the angles between each of them define the so-called unit cell parameters: *a*, *b*, and *c* (in Ångström); α , β , and γ (in degrees). Their directions are the crystallographic axes and are often symbolized respectively by *X*, *Y*, and *Z*.

The faces of the unit cell facing **a**, **b**, and **c** are respectively named A, B, and C. There are seven shapes of unit cells possible in terms of the symmetry requirements that can fill the three-dimensional space. They are referred to as the seven crystal systems (Table 1). It is worth pointing out that some trigonal lattices can be described by a P cell of rhombohedral shape.

When the unit cell is defined by one equivalent point at each corner, it is called a primitive cell. It is symbolized by the letter P (Table 2). When the unit cell is defined by one equivalent point at each corner and on the center of one face, it is called face-centered cell. Depending on which face is centered, the symbol used will be A, B, or C. When a P cell has an additional equivalent point in the middle of the cell, it is called a body-centered cell and given the symbol I. When the cell has equivalent points at each corner and in the center of each face, it is called all-faces-centered cell and is

denoted by F. Finally, the symbol R designs a rhombohedrally centered cell.

When all the possible different cells centering for each of the crystal systems are combined, a total of 14 different space lattices is possible. These are called Bravais lattices (Table 3).

As mentioned earlier in text, the unit cell of a crystal must reproduce itself regularly on a lattice. This restricts, in fact, the number of distinct symmetry operations. Only 10 are to be considered (Table 4).

It is known that there are only 32 unique ways of combining these symmetry elements that can describe a crystal (i.e., repeat in three-dimensional to fill space). These 32 combinations are called point groups (or crystal classes) and are presented in Table 5. The point groups are implicitly inherent to the definition of the crystal

Figure 7 Notation for a unit cell.

Table 1 The seven crystal systems

Crystal system	Length property	Angle property
Triclinic	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma \neq 90^\circ$
Monoclinic	$a \neq b \neq c$	$\alpha = \gamma = 90^\circ; \beta \neq 90^\circ$
Orthorhombic	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Tetragonal	$a = b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Trigonal (hexagonal)	$a = b \neq c$	$\alpha = \beta = 90^\circ; \gamma = 120^\circ$
Trigonal (rhombohedral)	$a = b = c$	$\alpha = \beta = \gamma \neq 90^\circ$
Hexagonal	$a = b \neq c$	$\alpha = \beta = 90^\circ; \gamma = 120^\circ$
Cubic	$a = b = c$	$\alpha = \beta = \gamma = 90^\circ$

Table 2 The conventional types of unit cell

Type	Symbol	Positions of additional lattice points	Number of lattice points per cell
Primitive	P	None	1
A-face centered	A	0, 1/2, 1/2	2
B-face centered	B	1/2, 0, 1/2	2
C-face centered	C	1/2, 1/2, 0	2
Body centered	I	1/2, 1/2, 1/2	2
All faces centered	F	1/2, 1/2, 0; 1/2, 0, 1/2; 0, 1/2, 1/2	4
Rhombohedrally centered	R	1/3, 2/3, 2/3; 2/3, 1/3, 1/3	3

systems because the shape of the unit cell is really the result of symmetry and not the opposite.

In reality, in addition to the operation of the point group, crystals have the possibility of a different type of

Table 5 List of the 32 point groups

Crystal system	Possible point groups
Triclinic	$1, \bar{1}$
Monoclinic	$2, m, 2/m$
Orthorhombic	$222, mm2, mmm$
Tetragonal	$4, \bar{4}, 4/m$ $422, 4mm, \bar{4}2m, 4/mmm$
Trigonal	$3, \bar{3}$ $32, 3m, \bar{3}m$
Hexagonal	$6, \bar{6}, 6/m$ $622, 6mm, \bar{6}2m, 6/mmm$
Cubic	$23, m\bar{3}$ $432, \bar{4}3m, m\bar{3}m$

symmetry called translational symmetry. This type of symmetry involves the definition of two new symmetry elements: screw axes and glide planes. These both are a combination of a rotation and a translational movement. The former rotates a point around an axis (rotation of $360/n^\circ$, n being any integer from 1 to 6) and then translates it parallel to the axis by a certain fraction cell distance (translation of k/n , where k is an integer and is inferior to n); it is written as n_k . The latter reflects a point through a plane and then translates it parallel to the plane halfway along one or two of the crystallographic axes. The symbol of a glide plane is given by the direction of the translation (i.e., a glide plane type a corresponds to a translation of $a/2$).

There are 11 screw axes ($2_1, 3_1, 3_2, 4_1, 4_2, 4_3, 6_1, 6_2, 6_3, 6_4$, and 6_5) and 5 glide planes (a, b, c, n , and d). A glide plane type n translates along the half of a diagonal of a face (e.g., $a/2 + b/2$), and d translates along a fourth of either a face or a space diagonal of the unit cell.

By combining these new symmetry elements with the Bravais lattices and the 32 point groups, there are exactly 230 combinations that can describe the symmetry of a crystal (Figure 8). They are called space groups.

Table 6 presents the space groups of triclinic, monoclinic, and orthorhombic systems. For molecular solids, the space groups of these systems account for more than 92% of all structures solved.

The space group symbol consists of a letter indicating the type of cell centering followed by a set of symbol corresponding to the symmetry elements present in the cell (Hermann–Mauguin notation). It is worth pointing out that all symmetry elements are not be necessary explicitly mentioned in the symbol. The conventions used for the space group symbols in each system are discussed in the following paragraphs.

For triclinic space groups, only two possible symmetries can occur: 1 and $\bar{1}$. As a result only two space groups exist: P1 and $P\bar{1}$ (as a general rule, when a center of symmetry is present, it will be placed at the origin of the unit cell).

Figure 8 Element combinations to generate the 230 crystallographic space groups.

Table 6 Space groups for triclinic, monoclinic, and orthorhombic systems^a

Crystal system	Point group	Space group
Triclinic	1	P1
	$\bar{1}$	P$\bar{1}$

^aSpace groups without inversion centers or mirror planes are shown in bold.

For monoclinic groups, the symmetry along the *b*-axis is generally given (twofold axis parallel to **b**, symmetry plane normal to **b**). The various groups are composed of all possible combinations of the elements of the point group 2, m, and 2/m and the corresponding translational elements 2₁, c, 2₁/m, 2/c, and 2₁/c. When the space group contains both a rotation axis and a symmetry plane related to the same direction, it is conventional to write the symbols corresponding to these symmetry elements separated by the symbol '/'. Thus, C2/c means C face-centered cell, twofold axis along **b**, glide plane of type c normal to **b**.

For orthorhombic groups, the symmetry along the *a*, *b*, and *c* axes is given (twofold axis parallel to the axis, symmetry plane normal to the axis). Thus, Pna2₁ means primitive cell, glide plane of type n normal to **a**, glide plane of type a normal to **b**, and twofold screw axis along **c**.

For tetragonal, trigonal, and hexagonal groups, the symmetry along the *c* axis is given first. The next symbol in the space group will refer to the symmetry along *a* (and *b* because *a* = *b*). The third symbol, when present, will refer to the *ab* diagonal direction ([110]). Thus, P4₂/mbc (tetragonal system) indicates a primitive cell, a 4₂ screw axis along **c** to which a mirror plane m is perpendicular, a glide plane type b normal to **a**, and a glide plane type c normal to [110].

For cubic groups, the symmetry is given first along the *a* (*b* and *c*) axes. The next symbol refers to the body diagonal [111] and is always a 3 (or $\bar{3}$). The last symbol refers to the face diagonal direction [110].

Symmetry and Structure Factors Calculation

For some particular set of reflections, the cell centering, the screw axes, and the glide planes lead to a structure factor of value 0. This is referred to as systematic absences. Systematic absences play a crucial role in the determination of a space group.

Table 7 lists all the possible absences. They all can be easily derived by using the algebraic form of the structure of eqn [31]. An example is shown in the following paragraph.

Let us suppose that a 2₁ screw axis is parallel to the *b* axis and located at 0 for the *a* and *c* axes. The symmetry equivalent point of (*x*, *y*, *z*) will be (−*x*, *y* + 1/2, −*z*).

Using eqn [32], $F(hkl)$ can be written as:

$$F(hkl) = \sum_{j=1}^{N/2} f_j \exp i 2\pi (bx_j + ky_j + lz_j) + \sum_{j=1}^{N/2} f_j \exp i 2\pi [-bx_j + k(y_j + 1/2) - lz_j]$$

To calculate specifically $F(0k0)$, the previous expression becomes:

$$F(0k0) = \sum_{j=1}^{N/2} f_j \exp i 2\pi (ky_j) + \sum_{j=1}^{N/2} f_j \exp i 2\pi [k(y_j + 1/2)] = \sum_{j=1}^{N/2} f_j \exp i 2\pi ky_j (1 + \exp i \pi k)$$

If *k* is odd:

$$F(0k0) = \sum_{j=1}^{N/2} f_j \exp i 2\pi ky_j (1 + \exp i \pi k) = \sum_{j=1}^{N/2} f_j \exp i 2\pi ky_j (1 - 1) = 0$$

If *k* is even:

$$F(0k0) = \sum_{j=1}^{N/2} f_j \exp i 2\pi ky_j (1 + \exp i \pi k) = \sum_{j=1}^{N/2} f_j \exp i 2\pi ky_j (1 + 1) = 2 \sum_{j=1}^{N/2} f_j \exp i 2\pi ky_j \neq 0$$

Table 7 Systematic absences – conditions indicate which reflections will exist

<i>Symmetry elements</i>	<i>Symbol</i>	<i>Set of reflections</i>	<i>Conditions for reflections</i>
Lattice	P	hkl	None
	A		$k + l = 2n$
	B		$h + l = 2n$
	C		$h + k = 2n$
	I		$h + k + l = 2n$
	F		hkl all odd or all even
Glide plane normal to <i>a</i>	b	0kl	$k = 2n$
	c		$l = 2n$
	n		$k + l = 2n$
	d		$k + l = 4n$
Glide plane normal to <i>b</i>	a	h0l	$h = 2n$
	c		$l = 2n$
	n		$h + l = 2n$
	d		$h + l = 4n$
Glide plane normal to <i>c</i>	a	hk0	$h = 2n$
	b		$k = 2n$
	n		$h + k = 2n$
	d		$h + k = 4n$
Glide plane normal to [110]	c	hhl	$l = 2n$
	d		$2h + l = 4n$
Screw axis parallel to <i>a</i>	2 ₁ , 4 ₂ , 6 ₃	h00	$h = 2n$
	3 ₁ , 3 ₂ , 6 ₂ , 6 ₄		$h = 3n$
	4 ₁ , 4 ₃		$h = 4n$
	6 ₁ , 6 ₅		$h = 6n$
Screw axis parallel to <i>b</i>	2 ₁ , 4 ₂ , 6 ₃	0k0	$k = 2n$
	3 ₁ , 3 ₂ , 6 ₂ , 6 ₄		$k = 3n$
	4 ₁ , 4 ₃		$k = 4n$
	6 ₁ , 6 ₅		$k = 6n$
Screw axis parallel to <i>c</i>	2 ₁ , 4 ₂ , 6 ₃	00l	$l = 2n$
	3 ₁ , 3 ₂ , 6 ₂ , 6 ₄		$l = 3n$
	4 ₁ , 4 ₃		$l = 4n$
	6 ₁ , 6 ₅		$l = 6n$
Screw axis parallel to [110]	2 ₁	hh0	$h = 2n$

So a screw axis 2₁ parallel to *b* creates a systematic absence on 0k0. Only reflections with $k = 2n$ exist.

Workflow in Small Molecule Structure Determination

A typical workflow for a small molecule diffraction experiment is shown in **Figure 9**. Each of the steps is described in more detail in the following sections and will relate to the use of charge-coupled device (CCD) detector diffractometers, which have nowadays displaced single-point detector diffractometers. These types of diffractometers have also introduced a large degree of automation and make the diffraction experiment more a black box. The reader is invited to refer to the section 'Further Reading' for more information on each of the steps.

At this stage, it is assumed that the user has already chosen the conditions under which the diffraction experiment is going to be run (wavelength, temperature, pressure, etc.). If the choice of the wavelength (Cu or Mo)

is being debated, **Table 8** can be referred to, which presents the main advantages of choosing one wavelength over the other depending on some parameters.

Crystal Selection

The main tool for evaluating the quality of a crystal is simply visual examination of it under a microscope (up to $\times 40$ magnification, with a strong light source and if possible with a polarizing attachment). Crystals with 'nice shape' are usually a good sign. Look for any other potential crystals stuck on the crystal selected. If so, and if they cannot be easily removed, choose another sample. In some cases, using a polarizer can help this investigation.

For organic compounds, crystals of size $0.1 \times 0.1 \times 0.1 \text{ mm}^3$ usually give good data with conventional laboratory instruments (with either Cu or Mo radiation) and in a relatively 'short' space of time (a couple of hours with CCD detector diffractometers). Smaller crystals are not necessarily a problem; the duration of the data collection will just be longer.

Figure 9 Typical workflow in small molecule X-ray crystallography.

Crystal Mounting and Positioning in the Beam

For crystals that are stable at ambient temperature and are not hygroscopic or light or air sensitive, the process of mounting is relatively simple. The crystal is fixed securely with a convenient adhesive (e.g., superglue for room temperature study or oil for low-temperature study) onto a glass fiber (or rigid fabric fiber), which is in

turn glued into a small cylindrical rod that fits into the well of the goniometer head. The aim is to make sure that the crystal does not move with respect to this head. A compromise has to be struck between a thick fiber (which will introduce absorption problems and background effects) and a very thin fiber (which can allow the crystal to vibrate, especially with the use of a stream of cold gas for low-temperature study).

Table 8 Guidance in choosing the wavelength of beam

Type of samples to deal with	Optimal wavelength
Organic compound with long unit cell ($> 30 \text{ \AA}$)	Cu
Weak diffracting organic compound	Cu (bigger diffracted intensities)
Absolute configuration wanted	Cu
Organic compound containing heavy atom	Mo (minimize absorption)
Metal complex	Mo (minimize absorption)
High-resolution, low-temperature studies	Mo

Ideally, the glass-fiber device should have been prepared well in advance and checked for potential problems (length of the fiber too short or too long and thus preventing the crystal to be later positioned correctly into the X-ray beam).

When placing the crystal onto the fiber, make sure that no crystal axis aligns perfectly with the fiber as this can enhance some errors (Renninger effect, etc.). If the crystal is air sensitive, it will have to be sealed into a capillary tube made of Lindemann glass (ideally with walls as thin as practicable). The fiber-rod device is then placed into the well of the goniometer head and the latter placed on the diffractometer. The crystal is positioned at the center of the beam optically so that its center does not move when the angle Φ of the diffractometer is rotated. This is an iterative procedure, and the exact methodology depends on the diffractometer. Usually the crystal will be viewed at $\Phi = 0^\circ$ and 180° , repositioned if necessary, then viewed at $\Phi = 90^\circ$ and 270° , repositioned if necessary, then checked again for $\Phi = 0^\circ$ and 180° , and so on. The positioning is done in practice by adjusting some translation screws of the goniometer head for each of the relevant positions.

Once the crystal has been correctly positioned, a small oscillation exposure can be recorded in a matter of a few seconds (10 s). This will give an almost instantaneous indication of the quality of the crystal (poor crystallinity, reflections split, etc.) together with the level of intensity diffraction (strong or weak). If the quality is judged poor, the selection of another crystal is required.

Determination of the Unit Cell

This step relies on the collection of a series of short exposure frames (usually 10), which takes a few minutes. As an example, with a scan angle of 1° per frame and an integration time of 20 s per degree, the acquisition of a 10-frames series may take only 5 min (κ -CCD diffractometer with Mo radiation). After the acquisition, the control program will automatically go through each frame, locate reflections (~ 100 reflections compared with 25 on a single-point detector diffractometer), and

yield coordinates of these observed reflections in reciprocal space. Then, the reflections will be indexed (hkl obtained) and will be followed by the determination of a crystal orientation matrix, the cell parameters, and the point group.

It is always useful at this point to visualize the frames and superimpose on each of them the positions of the reflections proposed by the cell determination (this is usually available through the control software). The positions relating to the cell parameters determined should overlay perfectly the intensities observed. If this is not the case, there is a problem: the cell obtained is probably wrong.

Crystals are not always perfect; all the unit cells are not perfectly aligned. The width of the distribution of misorientation angles of all the unit cells in a crystal is called mosaicity and is expressed in degrees. High mosaicity will have the effect of broadening the reflections and therefore impinge on the extraction of the intensities from the raw frames. Therefore, it must be determined before full data collection. In practice, it is assessed during the determination of the unit cell. For organic and organometallic crystals, a typical mosaicity falls in the range 0.4° – 0.8° . Values much higher than this indicates a problem with the crystal and the unit cell proposed.

Another useful check is to establish whether the cell volume is compatible or not with the molecular formula expected by comparing this volume with the molecular volume. As a rough approximation, for organic and organometallic compounds but not for purely inorganic ones, the molecular volume can be expressed as $18 \times \text{number of non-H atoms} \times Z$, where Z is the number of formulae per unit cell. A discrepancy between these two volumes means that either the cell is wrong or the proposed formula is not correct (wrong or right molecule but presence also of guest molecule(s) in the unit cell).

Data Collection

Following the cell determination, some parameters need to be set before starting the full data collection. Some of them will be chosen on the basis of the preliminary frames acquisition. These parameters are as follows:

- *Exposure time*: its choice will impact on the overall level of reflection intensities. In some control programs, an interactive tool guides you in choosing an appropriate exposure time. The tool can estimate the maximum exposure time before which overflow of the detection system can occur and the maximum theta value (with the resolution) at which data might be obtainable for a given exposure. Choosing a correct exposure time is often a compromise between these two factors. An exposure of 20 s is quite common.

- *Scan angle per frame*: in practice, each individual frame is measured over a small range of one goniometer axis. The scan angle is related to the mosaicity of the crystal, so the value of the angle should be at least the value of the mosaicity.
- *Detector to crystal distance*: for crystals with long cell parameters ($>30 \text{ \AA}$), it is sometimes useful to increase this distance to better separate the reflections.
- *Strategy*: some diffractometers have more than one set of goniometer head movements that can be chosen for a data collection to achieve the requested completeness and redundancy ($\Phi + \Omega$ scans, or Ω scans, etc.).

The data collection itself is fully automatic and often takes only a few hours ($\sim 3 \text{ h}$) for most well diffracting low-symmetry organic crystals. Presence of heavy atoms or higher symmetry may decrease this time, whereas smaller size or poorer diffracting crystals will increase it.

The advantage of CCD detector diffractometers is the high degree of data redundancy: many symmetry equivalent reflections are measured, and some reflections are measured many times in different positions, reducing systematic errors.

Data Reduction

The raw frames acquired during the data collection need to be processed in order to extract from them the integrated intensities. This will usually be done using integration software from the diffractometer manufacturer. It will use the orientation matrix obtained during the unit cell determination to determine the reflection positions and their intensities. The Lorentz and polarization corrections are automatically applied. In some cases, an absorption correction needs to be applied.

Space Group Identification

At this stage, following the previous step, a file containing a list of hkl reflections together with their intensities should have been generated. A qualitative examination of the diffraction intensities and an analysis of any potential systematic absences lead to the identification of the space group. Like the previous steps, this process is usually made effortless by the use of automatic software tools.

The data set is now ready for the next step, which is crystal structure determination. This step will be based on the solution of the ‘phase problem.’ Different methods exist to do so (Patterson method, direct method, charge flipping, etc.). They are readily available through software purely dedicated to crystal structure determination (SIR and SUPERFLIP) or part of a more complete crystallographic package software like CRYSTALS and SHELX. The most common methods, that is, Patterson and direct methods, are discussed in the following sections. The reader is encouraged to refer to the section ‘Further

Reading’ for more information on the most recent method: the charge flipping method.

Crystal Structure Determination: Patterson Method

The Patterson method is named after its creator, A. Patterson. It is based on a very simple concept: the ignorance of the phase problem. Patterson decided to concentrate his efforts on looking at what can be learned from the observed intensities only. He defined a function, called the Patterson function (symbolized by $P(uvw)$), which is the self-convolution of the electron density and displays a set of interatomic vectors. The Fourier transform of this function results in the intensities.

$$P(uvw) = \frac{2}{V} \sum_b \sum_k \sum_l |F(bkl)|^2 \cos 2\pi(bu + kv + lw) \quad [48]$$

where u , v , and w are the coordinates of a vector. The Patterson function will have maxima when the vector defined by u , v , and w corresponds to an interatomic vector.

Vectors between an atom and one of its symmetry equivalents are known as Harker vectors. It is also worth pointing out to the fact that the Patterson function is centrosymmetric.

By moving in turn each interatomic vector to the origin of the unit cell (without changing its direction), a map is built, which is called the Patterson map.

The Patterson map has the following characteristics:

- For N atoms in the unit cell, there will be N^2 possible peaks in the vector map, of which only $N(N - 1)$ corresponds to non-origin peaks.
- The height of each peak is proportional to the product of the atomic numbers of the atoms connected by the interatomic vector, multiplied by the multiplicity of the same vector.
- The peak at the origin will be large and proportional to $\sum Z^2$ for all atoms in the unit cell.
- The map always has an inversion center at the origin.

This method is particularly suited for crystal structures containing a heavy atom. In this case, it is often referred as ‘the heavy atom method.’

Crystal Structure Determination: Direct Methods

Direct methods are those that are trying to determine the structure factor phases directly from the observed intensities through mathematical relationships.

It has been shown in the Electron Density section that the amplitudes and phases of the structure factors are related through the electron density. If no information is held on the electron density, the amplitudes and phases cannot be calculated from each other. However, some

information, although not complete, is known about the electron density, and this facilitates the determination. If the amplitudes are known then the phases can be calculated from it (and vice versa).

The main types of information available on the electron density are as follows:

- *The electron density is composed of discrete atoms.* As a consequence, for a structure with well-resolved and almost equal atoms (which is a good approximation for organic compounds), the electron density and the squared electron density have maxima (peaks) at the same positions. In terms of structure factors, it is expressed as:

$$F(hkl) = \frac{f_{hkl}}{g_{hkl}} \sum_{b'k'l'} F(b'k'l') F(b-b', k-k', l-l') \quad [49]$$

where f_{hkl} is the atomic scattering factor and g_{hkl} the scattering factor of the 'squared' atom. Equation [49] is known as the Sayre equation.

If eqn [48] is multiplied on both sides by $F(-b-k-l)$ and if $|F(hkl)|$ and $|F(b-b', k-k', l-l')|$ have large values, it can be deduced that:

$$\varphi_{hkl} + \varphi_{b'k'l'} + \varphi'_{b-b', k-k', l-l'} \approx 0 \quad [50]$$

- *The electron density is positive.*
- *The structure is assumed to consist of a random distribution of atoms;* the probability distribution of structure factor amplitudes depends on whether the crystal possesses an inversion center (centric distribution) or not (acentric distribution).

The normalized structure factors have a mean value of 1 for all values of $\sin \theta$. The probability distributions of normalized structure factors are therefore:

$$P_1(E) = 2|E|\exp(-|E|^2) \text{ for acentric} \quad [52]$$

and

$$P_1(E) = \sqrt{2/\pi} \exp(-|E|^2/2) \text{ for centric} \quad [53]$$

The main steps undertaken during a typical structure determination by direct methods are summarized in **Figure 10**.

The first step will consist in the calculation of the normalized structure factors as stated in eqn [50]. The probability distribution of normalized factors will then be determined together with a scale factor (which allows the scaling of measured data to their absolute value) and the temperature factor B (defined in eqns [13] and [14]). The last two factors are determined by:

$$\ln \left(\frac{\langle |F_{\text{obs}}|^2 \rangle}{\sum_{j=1}^N f_j^2} \right) = \ln k - 2B \left\langle \frac{\sin^2 \theta}{\lambda^2} \right\rangle \quad [54]$$

In practice, the term on the left-hand side of the equation is plotted versus $\sin^2 \theta / \lambda^2$. The intercept of the best straight line passing through the datapoints on the vertical axis will give the $\ln k$, whereas the slope will give the value for $2B$.

The tangent formula is the key for the solution of structures by direct methods. It is used to calculate the phase of the sum represented by the Sayre equation and is given by:

$$\tan \varphi(hkl) \approx \frac{\sum_{b'k'l'} |E(b'k'l')E(b-b', k-k', l-l')| \sin[\varphi(b'k'l') + \varphi(b-b', k-k', l-l')]}{\sum_{b'k'l'} |E(b'k'l')E(b-b', k-k', l-l')| \cos[\varphi(b'k'l') + \varphi(b-b', k-k', l-l')]} \quad [55]$$

These probabilities depend on the structure factors and the atomic scattering factors. To remove the effect of the shape of the scattering factors from any further calculations ($\sin \theta / \lambda$ effects), it is customary to use a normalized structure factor $E(hkl)$ defined as:

$$|E(hkl)|^2 = \frac{|F(hkl)|^2}{\varepsilon(hkl) \sum_{j=1}^N f_j^2} \quad [51]$$

where $\varepsilon(hkl)$ is a factor that accounts for the space group symmetry effect on the observed intensities. The denominator can be considered as the expected intensity for the hkl reflection, and is often written as $\langle I \rangle$.

In other terms:

$$\varphi(hkl) \approx \varphi \left[\sum_{b'k'l'} E(b'k'l') E(b-b', k-k', l-l') \right] \quad [56]$$

It is possible to solve structures (small) starting from random phases by repeated application of this equation.

Crystal Structure Refinement and Validation

Most of this step is covered in details elsewhere in this encyclopedia (please consult the *See also* list at the end of this article). Only the main features are presented briefly in this article.

Figure 10 Workflow for direct methods. FOM stands for figure of merit.

The structural models obtained by the methods detailed in the Crystal Structure Determination sections in text (Patterson and direct methods) are often only a crude image of the real structure. In most cases, they are incomplete in the sense that not all the atoms have been located.

One common method to locate missing atoms is a difference Fourier synthesis method. It consists in the calculation of the difference series (O refers to observed, c to calculated):

If an atom is missing in the model then $\rho_c(xyz)$ will be 0 at the corresponding position, whereas $\rho_o(xyz)$ will show a maximum for the same position. The difference will therefore show a peak at this position. If the model is correct, the difference will be 0 (or close to 0) at all other positions.

Once the model is supposed complete, the next task is to adjust the various atomic parameters so that the calculated structure factors match the observed structure

factors as closely as possible. For this purpose, the atomic positions and thermal factors (either isotropic or anisotropic) will be subject to a process of refinement. This is usually done through the least-squares method.

The minimization function in least-squares refinement is either:

$$\rho_o(xyz) - \rho_c(xyz) = \frac{1}{V} \sum_{hkl} (|F_o(hkl)| - |F_c(hkl)|) \exp[-i2\pi(hx + ky + lz) + i\phi_c(hkl)] \quad [57]$$

$$\sum w(|F_o| - |F_c|)^2 \quad [58]$$

or

$$\sum w(F_o^2 - F_c^2)^2 \quad [59]$$

where w is an assigned weight for each reflection (different types of weighting schemes exist).

The Second function seems to be more popular nowadays because it allows all measured data to be used in the calculations, including the very weak reflections that may be discarded otherwise. In 2007, the guideline from *Acta Crystallographica* Section E set the number of reflections used in the refinement to be greater than the number of refined parameters by at least a factor of 10 if the structure is centrosymmetric, or by a factor of 8 if it is not.

Refining a crystal structure is usually a progressive process. Each stage makes the model structure a little bit more complex. As an example, the first few cycles of refinement will usually target the scale factor, the positions, and the isotropic thermal parameter of the non-hydrogen atoms. If convergence is observed, the refinement can also be introduced on the anisotropic thermal parameters. The next step could be the location and addition of hydrogen atoms and so on.

Another parameter that can be refined for non-centrosymmetric crystal structure is the Flack parameter, often noted x . This parameter will determine the absolute structure from which the configuration of a chiral compound can be deduced. It is defined by:

$$|F(hkl, x)|^2 = (1 - x)|F(hkl)|^2 + x|F(\bar{h}\bar{k}\bar{l})|^2 \quad [60]$$

where x is close to 0 when the model is of the same chirality as the crystal and $x = 1$ when the model has an inverted chirality compared to the crystal. In this case, the model needs to be inverted.

Various factors are calculated in order to check the progress of the refinement. They are:

$$R = \frac{\sum ||F_o| - |F_c||}{\sum |F_o|} \quad [61]$$

$$wR = \left[\frac{\sum w(X_o - X_c)^2}{\sum wX_o^2} \right]^{1/2} \quad [62]$$

$$S = \left[\frac{\sum w(X_o - X_c)^2}{(N - P)} \right] \quad [63]$$

where X refers either to $|F|$ or to F^2 depending on the method of refinement chosen. S is called the goodness of fit, and its value should be close to unity. R and wR should be as low as possible (usually an R value of 0.03 with $|F|$ refinement indicates a very good crystal structure model).

If the model does not lead to any convergence, it means that there is a problem. Apart from the fact that the model could be wrong, the most common problems encountered are presence of disorder in the structure or crystal twinning. Introduction of constraints/restraints in the refinement may help in solving the disorder problem. As for the twinning, the mathematical relationship between the two unit cell orientations (twin law) needs to be found in order to solve the problem.

The validation process can be of help by the use of some computing software. In particular, the crystallographic software package PLATON has, among other features, an exhaustive list of tools to check for any potential error in the crystal structure obtained (cell error, extra symmetry detected, void in the structure, problem of disorder, etc.).

δ	chemical shift
τ_1	relaxation time
ξ	angle between main axes of interaction tensors and sample spinning axis
χ	quadrupole coupling constant

Compared with solution NMR, the study of solid samples presents certain peculiarities derived from the nuclei being fixed at their lattice positions in a crystal. This rigidity gives rise to the effect of various anisotropic interactions in NMR spectra, the most common of which are given in **Table 1**. All these interactions produce orientation-dependent resonances, resulting in characteristic splittings and/or non-Lorentzian broadening of the solid-state NMR signals. The line broadening may range from a few ppm up to thousands of ppm, which helps to explain why much effort has been devoted to the development of line narrowing techniques.

Since ca. 1958, for example, Andrew and co-workers have pioneered a method known as magic-angle spinning (MAS), in which the sample is spun inside a suitable rotor, at an angle of 54.7° with respect to the external magnetic field B_0 (**Figure 1**). The expected effect of MAS is to average out the orientational dependence of NMR lines, rendering a solution-like spectrum where the relevant interactions are collapsed to their corresponding isotropic values (**Table 1**). Owing to the successful combination of MAS with sensitivity enhancement pulse sequences (most notably cross-polarization from abundant to dilute spins), solid state NMR has evolved into a technique with sensitivity and resolution comparable to its solution counterpart. It should be borne in mind, however, that MAS is successful provided two conditions are met. On one hand, the dependence of NMR transitions with the orientation should be of the form $(1 - 3 \cos^2\theta)$, otherwise split and/or broad lines may result. On the other hand, the frequency of sample spinning should be comparable or higher than the anisotropy. If this latter condition is not attained, the spectrum will show not only an isotropic resonance, but also a number of spinning sidebands separated from the latter by integer multiples of the spinning frequency. The presence of such a sideband manifold may in itself constitute a nuisance, but in certain circumstances it provides a means to measure interesting molecular properties.

The present article has been divided in two main sections, which are briefly described below.

- (1) When the observed nucleus is spin- $\frac{1}{2}$ and a neighbouring nucleus is quadrupolar, i.e. spin $> \frac{1}{2}$. In this case, the main interactions suffered by the nucleus

Table 1 Anisotropic interactions affecting NMR spectra in the solid state

Interaction	Parameter ^a					Average value in solution
	G Tensor	k	P	Anisotropy	Asymmetry	
Chemical shift	σ	$\gamma/2\pi$	B_0	$\Delta\sigma$	η	σ_{iso}
Direct dipolar coupling	D	D	S	$-3D$	0	0
Scalar coupling	J	1	S	ΔJ	η_J^b	J_{iso}
Quadrupole coupling ^c	q	$\frac{e^2 Q}{2S(2S-1)\hbar}$	$P = I = S$	$3q_{zz}/2$	η^{θ}	0

^aThe general form of the Hamiltonian is $h^{-1}H = k/GP$.

^bThe usual assumption is $\eta_J = 0$ and J coaxial with D .

^cThe anisotropy is defined as $\Delta q = q_{zz} - (q_{xx} + q_{yy})/2$, and the asymmetry as $3(q_{yy} - q_{xx})/2\Delta q$, where q_{xx} , q_{yy} and q_{zz} are the principal components of the q tensor. Q is the nuclear quadrupole moment and q_{zz} is the maximum value of the field gradient tensor q .

are the chemical shift and the dipolar coupling to neighbouring nuclei. One would expect a simple, solution-like spectrum if high-speed MAS was applied. However, a subtle combination of the dipolar coupling with quadrupole interactions at neighbouring nuclei leads to the appearance of additional splittings, which cannot be averaged by MAS. Interesting information concerning molecular and structural properties of solid materials has been gathered from the study of these splittings.

- (2) When the observed nucleus is itself quadrupolar. Here the quadrupole interaction is dominant, the others

Figure 1 Scheme showing how MAS is implemented: the sample is placed inside a rotor, which spins in the kHz range about an axis inclined at 54.7° with respect to the external magnetic field B_0 .

being usually very minor in comparison. Normal MAS speeds are much smaller than typical quadrupole couplings (which lie in the MHz range), producing an enormous number of sidebands, except in the case of the central transition of half-integer spins. In this latter case distinctive line broadening effects appear which cannot be completely removed by MAS. Methods to overcome these difficulties will be reviewed.

Quadrupole Effects on Spin- $\frac{1}{2}$ NMR Spectra

Simple MAS Spectra

In this section we explain the basis of the success of MAS in achieving spectral narrowing in solid-state NMR. When a single, observed spin- $\frac{1}{2}$ I nucleus is coupled to a single quadrupolar S nucleus, the complete Hamiltonian is:

$$H = H_Z(I) + H_Z(S) + H_{CS}(I) + H_{CS}(S) + H_D(I, S) + H_J(I, S) + H_Q(S) \quad [1]$$

where $H_Z(I)$ and $H_Z(S)$ are the Zeeman terms for nuclei I and S respectively. They are given by:

$$h^{-1}H_Z(I) = -\nu_{0I}I_z \quad [2]$$

$$h^{-1}H_Z(S) = -\nu_{0S}S_z \quad [3]$$

where $\nu_{0I} = \gamma_I B_0$ and $\nu_{0S} = \gamma_S B_0$ are the nominal NMR frequencies. The forms of the other Hamiltonian terms appearing in eqn [1] are summarised in **Table 2**.

The usual assumption in computing NMR spectral resonances is to consider that the Zeeman terms are dominant in eqn [1], and thus that first-order perturbation theory can be applied. Using the information given in **Table 2**, the NMR lines for an observed I nucleus are given by

$$\nu_I = \nu_{0I}[1 - \sigma_{\text{iso}}(I)] - m_S J_{\text{iso}} + [\Delta\sigma(I)\nu_{0I}/3 - m_S D'](1 - 3\cos^2\theta) \quad [4]$$

Table 2 Hamiltonian terms affecting an I,S spin system and secular contributions to the NMR spectra

Term	Interaction	Affected nucleus	Secular contribution to NMR spectra ^a
$h^{-1}H_{CS}(I)$	Chemical shift of I	I	$-\nu_{0I}[\sigma_{\text{iso}}(I) - \Delta\sigma(I)(1 - 3\cos^2\theta)/3]I_z$
$h^{-1}H_{CS}(S)$	Chemical shift of S	S	$-\nu_{0S}[\sigma_{\text{iso}}(S) - \Delta\sigma(S)(1 - 3\cos^2\theta)/3]S_z$
$h^{-1}H_D(I,S)$	Direct dipolar coupling ^{b, c}	I and S	$D I_z S_z (1 - 3\cos^2\theta)$
$h^{-1}H_J(I,S)$	Scalar coupling ^{c, d}	I and S	$J_{\text{iso}} I_z S_z - (\Delta J/3) I_z S_z (1 - 3\cos^2\theta)$
$h^{-1}H_Q(S)$	Quadrupole coupling ^e	S	$\frac{\chi}{4S(2S-1)}[3S_z^2 \cos^2\theta - S^2 + \frac{3}{4}(S_+ S_- + S_- S_+) \sin^2\theta]$

^aThe angle θ between the main tensor axes and the external magnetic field is characteristic of each interaction; the expressions shown in this table are valid only if the relevant tensors are axially symmetric and coaxial.

^b $D = (\mu_0/4\pi)(\gamma_I \gamma_S \hbar/4\pi^2 r_{IS}^3)$ is the dipolar coupling constant (r_{IS} is the internuclear distance).

^cThe secular contributions for these interactions are valid for heteronuclear spin systems. For homonuclear spin systems, the flip-flop term containing $(I_+ S_- + I_- S_+)$ is also secular.

^dThe usual assumption of J coaxial with D leads to an effective dipolar constant $D' = D - (\Delta J)/3$.

^eThe quadrupole coupling constant is defined as $\chi = e^2 Q q_{zz}/h$.

where $m_S = -S, -S+1, \dots, S-1, S$ are the spin components for nucleus S . Equation [4] is true provided the relevant tensors σ , D and J are axially symmetric and co-axial. Notice that the quadrupole interaction plays no role in eqn [4], owing to the fact that the latter does not contain I spin operators (Table 2). If MAS is applied at a sufficiently high speed, i.e. when the sample spinning frequency ν_r is larger than the effective anisotropy ($\Delta\sigma\nu_{0I} - 3m_S D'$), the factor $(1-3\cos^2\theta)$ in eqn [4] becomes $(1-3\cos^2\xi)$ [$1-3\cos^2(54.7^\circ)$]/2 (here ξ is the angle between the main axes of the interaction tensors and the sample spinning axis). Since $\cos^2(54.7^\circ) = \frac{1}{3}$, eqn [4] predicts, under MAS, a J -coupled multiplet centred at the isotropic I chemical shift:

$$\nu_I = \nu_{0I}[1 - \sigma_{\text{iso}}(I)] - m_S J_{\text{iso}} \quad [5]$$

i.e. a solution-like spectrum. This constitutes the basis of the successful applications of MAS which led to the development of high-resolution solid-state NMR.

When the spinning speed is low, the result is well known: the isotropic resonance appears flanked by a number of sidebands, located at integer multiples of the spinning frequency. Suitable analysis of the intensities of these sidebands allows of the chemical shift parameters $\Delta\sigma$ and η for nucleus I .

Second-Order Effects

The simple, solution-like eqn [5] was found to apply in most solid-state NMR spectra. However, conference reports in 1979, and papers in the scientific literature soon after, showed both experimentally and theoretically that this was not the case when the quadrupole interaction at a neighbouring S nucleus is comparable to its Zeeman interaction. To interpret these results, first-order theory needs to be corrected with second-order effects. The latter are the result of the interplay of the tensors D and q , through non-secular terms of the corresponding $H_D(I,S)$ and $H_Q(S)$ Hamiltonians (specifically, the single quantum transition terms containing the operators $I_{\pm}S_z$ and $I_zS_{\pm}$). They lead to the appearance of terms having an orientational dependence other than $(1-3\cos^2\theta)$, which cannot be averaged out even by high-speed MAS. Second-order theory allowed the derivation of the following simple equation:

$$\begin{aligned} \nu_I = \nu_{0I}[1 - \sigma_{\text{iso}}(I)] - m_S J_{\text{iso}} + \left(\frac{3D'\chi}{10\nu_{0S}} \right) \\ \times \left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \end{aligned} \quad [6]$$

From the second-order shift (the last term in the right-hand side of eqn [6]), the following six conclusions can be drawn.

- (1) Second-order effects scale inversely with the applied magnetic field, in contrast to J_{iso} or chemical shift

effects. Thus, experiments conducted at different fields provide evidence that the observed splittings are indeed due to quadrupole effects.

- (2) The second-order shifts depend on m_S^2 , and therefore their values occur in pairs. When $J_{\text{iso}} = 0$ (and ΔJ is also zero), eqn [6] predicts the I line as a 2:1 doublet for $S = 1$, and as a 1:1 doublet for $S = 3/2$ (Figure 2a and 2b). Simple equations for the doublet splittings s (Figure 2a and 2b) exist (eqn [6]): $s = 9D_\chi/10\nu_{0S}$ for $S = 1$, and for $s = 6D_\chi/10\nu_{0S}$ for $S = 3/2$. Notice that for $S = 1$ the doublet is asymmetric (Figure 2a), causing s to have a definite sign (the convention is that s is positive if the smallest peak appears at higher frequencies).

For a finite J_{iso} , the I line is predicted to be a distorted J -multiplet (Figure 2c and Figure 2d). Since the outermost lines of the multiplet shift in opposite direction as compared with the innermost lines, the spectra are 'bunched' at one end, in a manner which also depends on the sign of χ , the quadrupole coupling constant (Table 2).

It should be noticed that in all cases the lines are not single peaks but have a distinct powder pattern shape (Figures 3a and 4a).

- (3) The average of the second-order shifts over m_S is zero, and hence the isotropic $\sigma_{\text{iso}}(I)$ is obtained by averaging the multiplet line frequencies.
- (4) The value of J_{iso} is obtained by averaging the multiplet line spacings, or from the central spacing if S is half-integer (Figure 2c and 2d).
- (5) The sign of s or the sense of spectral 'bunching' provides experimental access to the sign of χ , which

Figure 2 Spectral appearance of the solid-state NMR spectrum of a spin- $\frac{1}{2}$ nucleus (I), including second-order quadrupole effects from S when: (a) $S = 1$, $J_{\text{iso}} = 0$; (b) $S = \frac{3}{2}$, $J_{\text{iso}} = 0$; (c) $S = 1$, $J_{\text{iso}} \neq 0$; (d) $S = \frac{3}{2}$, $J_{\text{iso}} \neq 0$. In all cases eqn [6] applies, with χ positive. The frequency axes increase from right to left.

Figure 3 (a) Powder pattern line shape of an I nucleus coupled to a quadrupolar ($S = 1$) nucleus when $(\chi/\nu_{\text{OS}}) = 1$, $J_{\text{iso}} = 0$. The frequency axis is in units of the dipolar coupling constant D . (b) Frequencies (in units of D) of the three lines expected for an I,S pair ($S = 1$) as a function of the ratio χ/ν_{OS} . The line positions marked with symbols have been obtained by full-matrix Hamiltonian calculations. The solid lines are the values given by eqn [6].

is difficult to obtain from other techniques. An exception is the 1:1 doublet for $S = 3/2$ and $J_{\text{iso}} = 0$, in which case the information on the sign of χ is lost.

- (6) If the molecular geometry and the quadrupole parameters are known, the observation of distorted multiplets may allow the determination of the asymmetry in the $\mathbf{J}$ tensor ΔJ .

When the assumptions of axial symmetry and coaxiality among the tensors are relaxed, the following general equation is obtained:

$$\begin{aligned} \nu_1 = & \nu_{01}[1 - \sigma_{\text{iso}}(\text{I})] - m_{\text{S}}J_{\text{iso}} \\ & + \left(\frac{3D'\chi}{20\nu_{\text{OS}}} \right) \left[\frac{S(S+1) - 3m_{\text{S}}^2}{S(2S-1)} \right] \\ & \times (3 \cos^2 \beta^{\text{D}} - 1 + \eta_{\text{Q}} \sin^2 \beta^{\text{D}} \cos 2\alpha^{\text{D}}) \end{aligned} \quad [7]$$

Equation [7] incorporates not only χ but also η_{Q} , as well as two angles (β^{D} and α^{D}) that fix the mutual orientation of $\mathbf{D}$ and $\mathbf{q}$. As expected, eqn [6] is a special

Figure 4 (a) Powder pattern line shape of an I nucleus coupled to a quadrupolar ($S = 3/2$) nucleus when $\chi/\nu_{\text{OS}} = 1$, $J_{\text{iso}} = 0$. The frequency axis is in units of the dipolar coupling constant D . (b) Frequencies (in units of D) of the four lines expected for an I,S pair ($S = 3/2$) as a function of the ratio χ/ν_{OS} . The line positions marked with symbols have been obtained by full-matrix Hamiltonian calculations. The solid lines are the values given by eqn [6].

case of eqn [7] when $\beta^{\text{D}} = 0$, i.e. when $\mathbf{D}$ and $\mathbf{q}$ are coaxial.

Finally, when the value of χ is larger than the NMR frequency ν_{OS} second-order theory breaks down, and one needs to resort to complete full-matrix Hamiltonian calculations, with the results shown in **Figure 3b** and **Figure 4b** for $S = 1$ and $S = 3/2$, respectively (in both cases $J_{\text{iso}} = 0$). As can be appreciated, for low values of the ratio (χ/ν_{OS}) the predictions of eqn [6] are in agreement with the full calculations.

It is important to note that the effects described by eqn [6] are only observed in rigid solids. Both in solution and in highly mobile solid phases, random molecular motions average out all anisotropic contributions, leaving only eqn [5] (a further motional effect may be a fast quadrupole relaxation on nucleus S, which would erase the multiplet structure of the I signal).

Experimental Examples and Applications

Tables 3 and 4 summarize nuclear, molecular and structural parameters as well as the spectral appearance for some studied spin pairs giving rise to second-order quadrupole effects on the I line, as described above. In the case of ^{13}C , ^{14}N , the ratios (χ/ν_{OS}) are low and have therefore been studied mainly on the basis of the simple eqn [6] (and its extension to non-symmetric q tensors); in most cases $J_{\text{iso}} = 0$ and $D' = D$ (see Table 2). The theoretical equations have been used (1) to predict the spectral appearance once the molecular geometry and the quadrupole parameters are known, (2) to derive approximate values of χ (including sign) from the spectra and (3) to aid in spectral assignment, since the affected carbons appear as characteristic doublets.

Most studies on ^{13}C , ^{14}N second-order effects were done using relatively low field solid-state NMR spectrometers. The advent of high-field instruments has displaced this interesting phenomenon to a rather unfortunate second place: at 7.05 T the effects are rarely seen, unless favourable circumstances occur. An interesting example is provided by a metal cyanide polymer, in which the molecular geometry suggests that all relevant tensors σ , D and q are axially symmetric and coaxial. The ^{13}C solid-state MAS NMR spectrum at 7.05 T and high spinning speed shows three asymmetric doublets (corresponding to non-equivalent cyanide sites), from which values of χ in the range -1.9 to -2.5 MHz have been derived (Figure 5). The sideband shapes are also doublets with characteristic line shapes, and have

Figure 5 Solid-state ^{13}C MAS spectrum of a sample of the polymer $[(\text{CH}_3)_3\text{Pb}]_4\text{Ru}(\text{CN})_6$ obtained at a nominal frequency of 75.43 MHz ($B_0 = 7.05$ T) and a spinning speed of 4.3 kHz, by summing all relevant sidebands. There are three different cyanide sites in the solid, each giving a characteristic (negative) splitting s .

been successfully simulated using second-order theory (Figure 6). This simulation also provided, as a by-product, $\Delta\sigma = 350$ ppm for the ^{13}C chemical shift tensor.

Another spin-1 nucleus causing second-order effects is ^2H (Table 3). ^{13}C MAS NMR spectra of solid deuterated organic molecules show distorted triplets, as expected from eqn [6] when $J_{\text{iso}} \neq 0$. In this case, the small value of χ for ^2H is compensated by a large dipolar coupling constant D (Table 4).

In the case of ^{13}C nuclei coupled to chlorine (Table 3), the values of (χ/ν_{OS}) for $^{35,37}\text{Cl}$ are such that 1:1 doublets are observed even at high fields, as described by eqn [6] when J_{iso} is negligible. On the other hand, in ^{119}Sn spectra of chlorostannic compounds, distorted quartets have been observed which allowed the determination of the parameter ΔJ (Table 4). Notice that axial symmetry and coaxiality of D and q are plausible assumptions for the X-Cl bond. Since the nuclear properties of both chlorine isotopes are similar (Table 3), only average effects are observed in the spectra, except in the special circumstances of very high spectral resolution.

When the quadrupolar nucleus is bromine, J_{iso} effects are important, and ^{13}C NMR spectra of C-Br carbons appear as asymmetrically distorted quartets (Figure 7). Further, the ratio (χ/ν_{OS}) is in this case large (Tables 3 and 4), and second-order theory cannot be applied. Thus, full-matrix calculations were used to account for the observed spectra, as well as a so-called 'inverse' first-order theory, in which the

Figure 6 Simulated shapes of the isotropic line and sidebands (as numbered) for the sample of Figure 5. The simulations were done assuming $\chi(^{14}\text{N}) = -2.3$ MHz and $\Delta\sigma(^{13}\text{C}) = 350$ ppm.

Zeeman term is considered as a small perturbation on the quadrupole Hamiltonian. In any case, knowing both the C–Br distance and Br quadrupole coupling constants, and assuming axial symmetry of all tensors around the C–Br

bond, allows one to derive approximate values of J_{iso} and ΔJ from the spectra (**Table 4**). As with chlorine, the separate effects of both bromine isotopes are difficult to distinguish (**Table 3**).

Finally, cases involving ³¹P coupled to metals should be mentioned. Spectra which involve coupling of ³¹P to several quadrupolar metals, e.g. ^{63,65}Cu ($S = 3/2$), ⁵⁵Mn ($S = 5/2$), ⁵⁹Co ($S = 7/2$) and ⁹³Nb ($S = 9/2$) have been found to consist of distorted *J*-multiplets, as expected from eqn [6]. The pair ³¹P, ^{63,65}Cu has been extensively studied in a series of phosphine–Cu(I) complexes. Since the ratio (χ/ν_{OS}) is low, second-order theory allowed the easy calculation of χ and ΔJ from the spectra (**Table 4**). It is interesting to note that solid-state NMR is one of the few techniques which allow one to measure ΔJ , a parameter of somewhat elusive experimental accessibility.

Self-Decoupling

As discussed above, second-order effects are only observed in rigid solid samples. Random molecular motions in solution or in highly mobile solids produce two phenomena: (1) anisotropic dipolar and quadrupolar interactions are averaged to zero (**Table 1**), and (2) fast longitudinal relaxation is induced on the quadrupolar nucleus *S*, leading to the collapse of all coupling interactions (both dipolar and scalar). The latter result is known as self-decoupling, and is responsible, for example, for why ¹³C nuclei in solution do not normally

appear as J -coupled when bonded to ^{14}N or $^{35,37}\text{Cl}$ nuclei. An interesting situation arises when the solid-state motion is anisotropic: the relevant interactions do not completely disappear, but are scaled down, depending on the extent of the motion. Only self-decoupling would be able to erase the expected splittings in this case.

Appropriate examples are provided by sodium chloroacetates. Both $\text{ClCH}_2\text{COONa}$ and $\text{Cl}_2\text{CHCOONa}$ show the ^{13}C -Cl signal as the expected 1:1 doublet and 1:2:1 triplet, respectively (provided second-order theory applies) (Figure 8a and 8b). However, Cl_3CCOONa shows a narrow single peak even at low temperatures (Figure 8c), owing to a fast rotation of the Cl_3C group around the C-C bond. That the collapse of the expected 1:3:3:1 quartet in the latter case is due to self-decoupling was confirmed by independently measuring the ^{35}Cl longitudinal relaxation times in all three salts by using nuclear quadrupole resonance. As expected, the ^{35}Cl T_1 in Cl_3CCOONa is significantly shorter than in other two compounds.

Quadrupole Effects on NMR Spectra from Nuclei with Spin $>\frac{1}{2}$

MAS Spectra

From the information given in Table 2, the following expression for the S NMR signal can be obtained when the observed nucleus is itself quadrupolar:

$$\nu_S = \nu_{\text{IS}}[1 - \sigma_{\text{IS}}(S)] - m_I J_{\text{IS}} + \left[\frac{3\chi(m_S + \frac{1}{2})}{4S(2S-1)} - \frac{1}{3}\Delta\sigma(S)\nu_{\text{IS}} \right] (1 - 3\cos^2\theta) \quad [8]$$

In general, the spectra are dominated by the quadrupole interaction (i.e. the term containing χ in eqn [8]). Although the relevant term in eqn [8] also contains the usual factor $(1 - 3\cos^2\theta)$, the ability of MAS to average out the quadrupole effects depends critically on the spinning speed. Typical values of χ lie in the MHz range; thus, at experimentally accessible spinning speeds (which rarely exceed tens of kHz) the spectra will have the signal intensity distributed over an enormous number of very weak sidebands. There is an exception to this rule: when $m_S = -\frac{1}{2}$ in eqn [8], the first-order quadrupole effect is zero, and MAS should yield simple spectra. Thus, efforts have been directed to the study of the central transition $(-\frac{1}{2}, +\frac{1}{2})$ in half-integer spin systems. Even when the first-order effect is zero for the latter transition, second-order quadrupolar effects remain which are not completely removed by MAS. The expression for the NMR central transition of half-integer quadrupolar nuclei with axially symmetric q , when

high-speed MAS is applied, is

$$\nu_S = \nu_{\text{IS}}[1 - \sigma_{\text{IS}}(S)] - m_I J_{\text{IS}} + \nu_{\text{IS}}\Delta\sigma_{\text{qs}} + \frac{1}{10}\left(\frac{\chi^2}{\nu_{\text{IS}}}\right)\frac{9[4S(S+1)-3]}{[16S(2S-1)]^2} \times (35\cos^4\xi - 30\cos^2\xi + 3) \quad [9]$$

where

$$\nu_{\text{IS}}\Delta\sigma_{\text{qs}} = \frac{3}{10}\left(\frac{\chi^2}{\nu_{\text{IS}}}\right)\frac{4S(S+1)-3}{[4S(2S-1)]^2}$$

is the so-called isotropic second-order quadrupolar shift and ξ is the angle between q_{zz} and the rotor axis. Equation [9] will conceivably lead to three effects (**Figure 9**): (1) broad powder pattern line shapes, (2) a shift $\Delta\sigma_{qs}$ of the centre-of-gravity of the spectrum with respect to the isotropic chemical shift, and (3) the occurrence of sidebands (notice that, according to **Table 5**, $\chi^2/\nu_{OS} \ll \chi$ and hence typical spinning speeds will lead to a reasonably low number of sidebands).

In general, appropriate spectral simulations based on eqn [9] are required to retrieve the relevant information concerning χ (and η_Q in non-symmetric cases), σ_{iso} and the chemical shift parameters $\Delta\sigma(S)$ (and η). Notice that the broadness of the lines may lead to substantial overlap, thereby complicating the spectral interpretation. **Figure 10** shows the theoretical effect in a spectrum with two overlapping lines, for typical parameters of ^{17}O in minerals. Complete separation of peaks is not achieved even at very high magnetic fields.

Double Rotation NMR and Other Techniques

A significant increase in the fundamental knowledge of quadrupole effects in NMR spectroscopy has taken place since about 1990. Various techniques have been developed to diminish the effects produced by the orientational dependence of eqn [9], or to separate chemical shift from pure quadrupole effects. The most successful seems to be double rotation (DOR), in which the sample spins simultaneously around two different ‘magic’ angles: 54.7 and 30.6°. The latter angle has the property that, for $\xi = 30.6^\circ$, the factor $[35 \cos^4 \xi - 30 \cos^2 \xi + 3]$ in eqn [9] is zero, leaving a simple spectrum where only the chemical shift and the isotropic second-order quadrupole shift remain. Further distinction of these shifts can be made by recording spectra at different magnetic fields. **Figure 11** shows an example of the dramatic reduction in line width which is attained by application of DOR to a solid sample.

Other relevant methods are (1) quadrupole nutation spectroscopy, a two-dimensional technique which allows the projection of the conventional spectrum in one dimension, and only quadrupolar information in the second frequency axis, (2) dynamic-angle spinning (DAS), in which the sample is spun sequentially rather than simultaneously (as in DOR) about two different ‘magic’ axes and (3) satellite transition spectroscopy (SATRAS), which monitors NMR transitions other than the central $(-\frac{1}{2}, +\frac{1}{2})$ under high-speed MAS, allowing the measurements of both the correct isotropic chemical shift and the quadrupole coupling in a single experiment.

A two-dimensional NMR method was introduced by Frydman and Harwood to obtain high-resolution spectra of half-integer spin quadrupolar nuclear systems. This method, called multiple-quantum magic-angle spinning (MQMAS), uses manipulation of spin coherences rather than the mechanical manipulation and rotation of the sample. Widespread applications include different types of materials such as glasses, clays, ceramics, zeolites, and organic, and biological substances. The most commonly observed nuclei are ^{11}B , ^{17}O , ^{23}Na , and ^{27}Al , but other examples exist for nuclei such as ^{25}Mg , ^{45}Sc , ^{51}V , ^{87}Rb , and ^{93}Nb . Further technical advances have resulted in different types of correlation experiments and investigation of higher-order terms and cross-terms among the

Table 5 Nuclear and field gradient properties for some quadrupolar nuclei

Nucleus	$\nu_{QS}(\text{MHz})^a$	S	Natural abundance (%)	$10^3 Q(S)$ (barn)	Range of $ I\chi $ (MHz)
^{23}Na	79.35	3	100	100.6	1–4

Table 6 Chemical shift range in solid materials studied by solid-state NMR of quadrupolar nuclei

Nucleus	Chemical shift range (ppm)	Usual reference	Studied materials
²³ Na	– 50–50	NaCl (1 M)	Na oxides and salts, zeolites
²⁷ Al	150–200 (tetracoord.) 20–80 (pentacoord.) – 20–50 (hexacoord.)	AlCl ₃ (1 M)	Zeolites, molecular sieves, catalysts, Al oxides, aluminates, Al glasses and ceramics
¹¹ B	– 2–2 (tetracoord.) 10–30 (tricoord.)	BF ₃ ·Et ₂ O	B glasses, oxides, borates
¹⁷ O	0–500	H ₂ O	Oxides, oxoanions, metal carbonyls
⁵¹ V	– 100–1000	VOCl ₃	V oxides, vanadia catalysts, vanadates
⁷ Li	– 5–5	LiCl (1 M)	Li glasses, oxides

various spin interactions. A related high-resolution technique is satellite transition MAS (STMAS) but this is still little used.

Studied Nuclei

The interest in studying quadrupolar nuclei with NMR is to combine useful chemical shift correlations with information concerning the quadrupole coupling constant. The value of χ depends on the nucleus itself (through the quadrupole moment Q), and on the maximum electric field gradient q_{zz} . The latter is a function of both the symmetry and the density of the electron distribution, i.e. on the molecular structure. For reasons discussed above, the focus has been restricted on the central transition of half-integer nuclei (which make up almost one-third of all NMR active nuclei). In this regard, ²³Na and ²⁷Al are the most studied, but interest has also been paid to ¹¹B, ¹⁷O, ⁵¹V and ⁷Li (see **Table 5** for nuclear and field gradient properties).

A great deal of attention has been paid to ²⁷Al, owing to its importance in the preparation and dealumination of zeolites, and in the study of inorganic materials and catalysts. Since the values of χ are relatively low (**Table 5**), the second-order quadrupole shift is small and therefore relatively narrow signals are obtained. Furthermore, the chemical shift range spanned by distinctly coordinated aluminium sites is large (**Table 6**), allowing not only the distinction of Al sites, but also environments within like sites which may differ in bond distances and angles or in hydrogen bonding. In fact, useful correlations between ²⁷Al chemical shift or quadrupole parameters and structural features have been found, such as (1) $\sigma_{\text{iso}}(^{27}\text{Al})$ varies linearly with Al–O–Al angles in aluminates and with Al–O–Si angles in aluminosilicates, and (2) $\chi(^{27}\text{Al})$ is linearly correlated with the distortion $|\psi| = \sum |\tan(\alpha_i) - 109.48^\circ|$ of the AlO₄ tetrahedron.

By studying other quadrupolar nuclei, interesting structural details have been obtained on a number of inorganic solids of undoubted technical importance, such minerals, zeolites, catalysts, ceramics, glasses and cements

(**Table 6**). Owing to the technological significance of the studied materials, it is likely that this area of solid-state NMR will experience great progress in the years ahead.

ω_r	rotation frequency

As in NMR of liquid samples, solid state NMR probes the magnetic interactions of atomic nuclei. These interactions yield detailed information about the local structure and dynamics of the sample, including the bonding types and geometry, the site–site connectivity patterns, and the spatial characteristics and timescales of atomic and molecular motions. All kinds of solids can be studied with NMR, including single crystals and powders, disordered materials such as glass and rubber, and metals and superconductors. Although not as high as in liquid state NMR, spectral resolution is still extraordinary (parts per million or better) but sensitivity is not. Sample volumes of order 100 μL are typical.

The magnetic interactions probed in solid state NMR include those studied in the liquid state, beginning with the Zeeman interaction between the nuclear spin and the applied magnetic field. This induces precession at the Larmor frequency ω_0 , which is defined by the nucleus and the strength of the external field. Fields as high as 21 T are in use, yielding proton Larmor frequencies of 900 MHz. Internal interactions observed include the chemical shift, and, in favourable cases, scalar couplings. Additionally, magnetic dipole and electric quadrupole interactions, which are observable only indirectly in liquid state NMR spectra, can be detected as frequency shifts in the solid state. In metals, the major spectral observable is the Knight shift. Because all these interactions depend sensitively on the local bonding geometry, they can be used to measure dynamic properties of the sample, either directly through spectral changes as a function of experimental parameters, or indirectly through the nuclear spin relaxation time.

The primary difference between solid state and liquid state NMR is one of timescale. The atomic dynamics of

the sample define a natural internal timescale, denoted τ . The motion of interest might be, for example, the rotational tumbling of molecules in a liquid, the reorientation of segments in a polymer, or the hopping of ions in a solid electrolyte. Clearly τ can range from picoseconds to seconds or more. As the observed nucleus moves to different locations or orientations, its NMR spectrum changes. This occurs both because the different sites may differ chemically, and also because the observable interactions are orientation-dependent, the sense of orientation being defined by the external magnetic field. The different orientations define a range of frequencies $\Delta\omega$ centred on the Larmor frequency. If $\Delta\omega\tau \ll 1$, then a given nucleus samples many local environments during the NMR experiment. All interactions that depend on molecular orientation are in this way averaged to zero, and the spectrum is ‘liquid-like’. ‘Solid-like’ spectra result when $\Delta\omega\tau \gg 1$, for then the anisotropic portions of the interactions remain. These include for example the above-mentioned magnetic dipole and electric quadrupole terms. Typical examples of both regimes are shown in **Figure 1**.

Figure 1 also shows the principal difficulty encountered in solid state NMR spectra: the additional information provided by the anisotropic interactions can seriously congest the spectrum, making interpretation difficult. Our aim in this article is to outline the current principal methods by which solid state NMR spectra can be acquired in interpretable form. Rather than giving an exhaustive account of the current developments in the field, we present the most important techniques in the context of the physical and chemical problems that they can help to solve.

Resolving Chemically Distinct Sites

The most frequent application of solid state NMR, as in the liquid state, is resolution of chemically distinct sites in a material. However, as **Figure 1** shows, the anisotropy observed in solid spectra typically creates so much spectral congestion that assignment is difficult. Moreover, as **Figure 1** also shows, the anisotropically broadened lines exhibit a variety of step and singularity features which, while informative in their own right, further obstruct a rapid assessment of the types and relative

Figure 1 (a) Typical chemical shifts of carbon in different functional groups. The line widths indicate the ranges observed; in a liquid sample, the actual line width will typically be much smaller. (b) Chemical shift powder patterns of carbons in the same functional groups. Such shapes are observed in powdered solids. The complex shapes, with steps and singularities, arise from the nontrivial orientation dependence of the chemical shift interaction, which is averaged to zero in a liquid but is observable in solids. The powder patterns are shown separately here for convenience; in real samples they overlap, making interpretation difficult. This problem is addressed by techniques such as magic angle spinning. Figure adapted from Schmidt-Rohr K and Spiess HW (1994) *Multidimensional Solid-State NMR and Polymers*. London: Academic Press.

concentrations of distinct sites. The most important method for improving resolution in solid state NMR is magic angle spinning (MAS). This method, so-called because the sample is rotated about an axis inclined at

the magic angle of 54.74° with respect to the magnetic field, can enhance the resolution by more than 2 orders of magnitude. It arises because the dominant anisotropies transform under rotations as 2nd rank spherical tensors, i.e. like d-orbitals. Recall that the d_z^2 orbital has an angular node; this is in fact at 54.74° . Thus an interaction which transforms in the same way can be averaged to zero by spinning about an axis located at this node.

To achieve effective averaging, the rotation frequency ω_r in MAS must be of the order of, or greater than, the spread of interaction frequencies: $\omega_r/\Delta\omega \gtrsim 1$. The resulting resolution enhancement is dramatic, as shown in Figure 2.

For nuclei like ^{13}C , ^{31}P , and ^{29}Si , which have modest chemical shift ranges, spinning frequencies of 5–10 kHz are often sufficient, and are well within range of typical commercial MAS probes. ^1H spectroscopy is particularly challenging in solid state NMR, in contrast to liquids, because of the strong magnetic dipole coupling between protons. This interaction gives a proton line width typically in the range of 20–50 kHz. Commercial MAS NMR probes are now available with spinning frequencies as high as 35 kHz, and so in many cases even ^1H solid state NMR can be accomplished with the MAS technique.

While MAS can provide significant resolution enhancement, it enhances sensitivity only insofar as the signal from broad resonances is concentrated into narrower resonances. For naturally low-abundance nuclei like ^{13}C (1% naturally occurring), this increase may be insufficient. For dilute spins in the presence of an abundant species with good sensitivity (such as protons), i.e. nearly all organic solids, double resonance methods may be used to achieve an additional gain in sensitivity. Coupled with MAS, these techniques are collectively referred to as CP-MAS (CP = cross-polarization). In CP-MAS, magnetization is first excited using the abundant species (typically ^1H), and then transferred to the dilute species (^{13}C or ^{15}N , say) by simultaneously irradiating both nuclei, at their respective Larmor frequencies. Then, the dilute spin is detected, often with decoupling of the abundant spin. All this is carried out in the presence of MAS, to obtain good resolution of the resulting spectrum. The theoretical sensitivity gain is the ratio of the Larmor frequencies of the two species, for example, 4 for the ^1H – ^{13}C pair. In practice, protons often have significantly shorter relaxation times than their CP partners, so this method also allows for shorter recycle delays in pulsed NMR, and thus more rapid acquisition of the spectrum. A disadvantage of CP-MAS is that the CP efficiency is a function of proximity of the abundant and dilute species, so that CP-MAS spectra cannot be assumed to be quantitative reflections of the abundances of the resolved sites.

While MAS and CP-MAS are often sufficient to resolve chemical sites for nuclei like ^{13}C , ^{31}P and ^{29}Si ,

Figure 2 The effect of magic angle spinning. The figure shows ^{31}P spectra of $\text{Na}_4\text{P}_2\text{O}_7 \cdot 10\text{H}_2\text{O}$, as a function of rotor frequency. Note the extreme line-narrowing achieved, while still in a powdered solid. This illustrates that the symmetry of the chemical shift interaction is such that the full isotropic averaging of the liquid state is more than necessary to suppress the anisotropy; rotation about a single axis is in this case sufficient. The small splittings show that crystallographically, as well as magnetically, different sites can be resolved. Figure adapted from Schnell I, Diploma Thesis, Johannes-Gutenberg-Universität Mainz, 1996; see also Kubo A and McDowell CA (1990) *Journal of Chemical Physics* 92: 7156.

this is not the case for other nuclei such as ^{27}Al , ^{17}O and ^{11}B . The reason is that the first group of nuclei have spin $\frac{1}{2}$, while the second have higher spin. Nuclei with spin greater than $\frac{1}{2}$ are subject to electric quadrupole effects, in addition to chemical shift, and these effects present a significant additional source of line-broadening. Because the quadrupole anisotropy in the presence of a strong magnetic field does not transform simply like a 2nd rank tensor, it cannot be removed completely by MAS alone. However significant progress has been made in devising methods to average quadrupole interactions in addition

to chemical shift anisotropy. Double rotation (DOR) and dynamic angle spinning (DAS) both make use of spinning the sample about a time-dependent axis. DOR is a direct extension of MAS, and makes use of a complex rotor-within-a-rotor device. In DAS, the sample spinning axis is hopped between two angles during the experiment. Both DOR and DAS require mechanically sophisticated probes. A third method, multiple-quantum magic angle spinning (MQ-MAS), uses just a MAS probe, but a complex pulse sequence to excite and detect triple and higher order coherences during the MAS experiment. It is mechanically the simplest to implement, but uniform excitation of different chemical sites is difficult with existing pulse sequences. Despite the limitations for each method mentioned above, they have yielded impressive resolution advances for quadrupolar nuclei (**Figure 3**), similar to what is achieved with MAS for nuclei such as ^{13}C .

The methods described above yield greatly enhanced resolution, and as such help to determine the types and amounts of distinct sites in material. This resolution gain comes at the price of discarding the information available from the interaction anisotropies. This information typically relates to the local site symmetry, for example, distortions in the bond angles, number of nearest neighbours, and so forth. Both high-resolution and interaction anisotropies may be obtained by taking advantage of a second spectral dimension, using so-called 'separation of interactions' experiments. An example is shown in **Figure 4**, where it is seen that the anisotropically broadened resonances are sorted according to their isotropic shift. In this way each resonance may be examined in isolation, and the anisotropy parameters determined with no congestion from neighbouring bands. There are many ways to implement such experiments; an elegant approach for simple chemical shift correlations is to spin the sample at an angle other than the magic angle during the first part of the experiment, followed by a hop to the magic angle and subsequent signal acquisition. In this way the anisotropic interactions 'label' the detected signal, and a double Fourier transform gives the type of spectra shown in **Figure 4**.

Determining the Connectivity between Sites

Once the types of sites in the material have been determined, using for example the techniques discussed above, the second step in determining the material structure can be considered, namely what the connectivity between these sites is. In liquid state NMR connectivities are primarily determined through scalar couplings, a through-bond interaction mediated by the electrons. However, this interaction is very small

Figure 3 ^{87}Rb NMR spectra of RbNO_3 . (a) The static spectrum. (b) The effect of magic angle spinning. The symmetry of strong quadrupole interactions is such that spinning about a single axis alone is not sufficient to remove all the anisotropy broadening. (c) Results of multiple-quantum magic angle spinning, one of several methods currently available to obtain high-resolution spectra of quadrupolar nuclei like ^{87}Rb . In this spectrum, the three crystallographically distinct rubidium sites are resolved, and the total line-narrowing is comparable to that achieved by MAS alone for spin $-\frac{1}{2}$ nuclei like ^{13}C and ^{31}P (see **Figure 2**). Figure adapted from Brown S, D. Phil. Thesis, Oxford University, 1998, and Brown S and Wimperis S (1997) *Journal of Magnetic Resonance* 128: 42–61.

compared to the anisotropies of the magnetic interactions, and so is hard to probe in solids in any but the most well-ordered samples. On the other hand, magnetic dipole interactions, i.e. the through-space effects of the nuclear magnetic moments on each other, can be substantial. This interaction varies with distance as r^{-3} , and so is of particular use in determining local structure. As noted above, dipole couplings are averaged to zero in 'liquid-like' spectra, but in solids they have easily observable effects on the resonance line shapes. Such interactions are also observed *indirectly* in liquids, through the nuclear Overhauser effect where they appear as second-order interactions and thereby survive the averaging due to the molecular motion. Knowledge of the through-space connectivities does not give directly a map

of the bonding network but, when combined with knowledge of the material composition and chemistry, can yield much about the bonding pattern.

For example, the CP-MAS experiment described above can be used to obtain some degree of through-space information. The magnetization transfer, from ^1H to ^{13}C say, is mediated by the magnetic dipole interactions. By varying the duration of the transfer time (usually called the contact pulse), sites can be distinguished by their transfer efficiency. For example, primary and secondary carbons can be selectively excited, relative to tertiary and quaternary carbons due to their greater proximity to protons. This is done simply by using a short contact pulse. Much more elaborate spectral editing schemes yield more accurate results, and are more flexible.

While variants of CP-MAS are particularly suitable for exploring proximities in heteronuclear systems with protons as one partner, other experiments can be performed to probe other heteronuclear systems, and homonuclear couplings. All make use of the dipole coupling as the mechanism for encoding distance information.

In general, one wants to combine the distance measurement with some kind of resolution enhancement, in order to determine which sites are close to which. This is not always possible. For example, in many inhomogeneous solids, only one (broad) resonance will be observed, even with MAS or similar techniques. A well-studied example is sodium in a glass. Because techniques like MAS average the dipole coupling to zero, if they do not provide sufficient resolution enhancement, they should not be used. Then, one studies a static sample. The spatial distribution of species in a static sample can be estimated, by measuring the decay properties of spin echoes.

In spin-echo experiments, an excitation pulse is followed at some time τ later by a refocussing pulse. At time τ , after the second pulse, an echo will typically form. The typical use of this experiment for measuring distances is to estimate the so-called second moment (M_2) of the resonance line. Interactions on a local scale, e.g. the chemical shift and quadrupole interactions, and interactions involving isolated pairs of spins, can be refocussed by using suitably chosen pulses. However, dipole coupling to a bath of partners cannot. Therefore, the echo cannot be refocussed indefinitely, but only up to a characteristic time which is a measure of properties of the bath of nuclei coupled to the studied species. The decay constant of the spin-echo envelope is proportional to M_2 , which is given essentially by summing over r_{ij}^{-6} , where the r_{ij} are internuclear distances. Because of the exponent -6 , this experiment gives short-range information. It is valuable in assessing qualitative features of the distribution of species in inhomogeneous materials.

Figure 4 A separation of interactions-type spectrum, of ^{29}Si in a glass. (a) By spinning the sample off the magic angle during the first part of the experiment, and on the magic angle in the second, a two-dimensional spectrum is generated that has a high-resolution dimension correlated with the anisotropies of the individual sites. (b) Here, in a glass, each site itself shows a distribution of environments, which can be mapped out quantitatively by taking slices through the two-dimensional spectrum. In this way, bond angle distributions for example, even in complex materials, can be determined, often with superior precision as compared to diffraction-based methods. Figure adapted from Zhang P, et al. (1996) *Journal of Non-Crystalline Solids* 204: 294–300.

An important extension of this experiment is called SEDOR, for spin-echo double resonance, in which an additional refocussing pulse is applied to a second nuclear species, and the echo behaviour with and without this secondary pulse is compared. In this way the mixing of different species in an inhomogeneous solid may be assessed.

Similar to SEDOR, but appropriate for isolated pairs of spins, is the rotational echo double resonance method, or REDOR. In REDOR, the combined dynamics of the isolated two-spin system and the sample rotation serve to generate echoes at the rotor period. These echoes can be dephased by application of a pulse to one of the coupled partners. The amount of dephasing caused by this additional pulse is a measure of the coupling strength, and hence proximity, of the spins in the pair. This experiment is most applicable to doubly labelled samples, e.g. biopolymers enriched at selected sites with ^{13}C and ^{15}N .

When the spectrum of the material consists of resolved resonances, much more detailed information on the nuclear distances can be derived than is possible with the spin-echo techniques outlined above. Magnetic dipole coupling is still the interaction to probe but, when the various sites are resolved, experiments can be used that give signals *only* if two distinct sites are near enough to each other to have a significant interaction. Clearly this yields much more detailed information than when the sites serve primarily to generate a background bath. Several types of signals can be generated and measured in this context, but the most precise are the so-called double-quantum coherences. Isolated nuclei (here we have in mind only spin $-\frac{1}{2}$, such as ^1H or ^{13}C) do not have enough energy levels to support quantum number changes greater than unity, and therefore also cannot support coherences greater than unity. If two such spins are coupled, however, the composite system can support

2-quantum coherence. Experiments can be designed that are selective only for 2-quantum coherence, thus yielding a connectivity map of the sites that are close enough spatially to couple in this way.

Generating such a connectivity map for a solid requires additionally a resolution-enhancement technique, such as MAS. Such techniques, as discussed previously, suppress precisely the spin–spin interactions that the connectivity map is meant to reveal. Therefore, to combine multiple-quantum experiments with MAS, a pulse sequence which counteracts the averaging effect of MAS, thereby restoring the dipole coupling, must be implemented during excitation and reconversion of the 2-quantum coherence. A variety of such dipolar

Figure 5 Double-quantum correlation spectrum of ^{31}P in a solid phosphate. At top (a) is the molecular fragment derived from assignment of the spectrum (oxygen atoms not shown), and includes phosphate chain branch points (site 3), branch connections (site 2) and chain phosphates (site 1). The spectrum (b) gives signals symmetric across the diagonal, for pairs of sites that are close enough in space to be coupled. Thus from such a spectrum the spatial proximity of resolved sites can be traced, as is done routinely in liquid NMR using scalar couplings (a through-bond interaction). Figure adapted from Feike M, et al. (1996) *Journal of the American Chemical Society* 118: 9631–9634.

recoupling sequences currently exist, of varying levels of performance and complexity.

The resulting two-dimensional spectra give a connectivity map that can be traced in much the same way as is routinely done for liquid samples (Figure 5).

It must be remembered, of course, that the signals observed reflect coupling through space, not through chemical bonds, so additional information about the chemistry must be used to interpret such spectra. Nevertheless, this method is fast becoming routine, as it requires only standard solids NMR instrumentation.

Dynamics in Solids

The dynamics of atoms in solids may be probed directly, through their effects on the NMR spectra, and indirectly, through the nuclear spin relaxation. Because the NMR

Figure 6 Two-dimensional wideline separation of interactions (WISE) spectrum of polystyrene-poly(dimethyl siloxane) diblock copolymer (PS-b-PDMS). In the first part of the experiment (a) proton magnetization is allowed to evolve, and then transferred to carbon in the second part of the experiment. In this way the proton spectra of individual carbon sites are sorted by the shift of each site, and the result is a wideline proton spectrum in one dimension, and a high-resolution MAS carbon spectrum in the other. In this example, (b), the PDMS is seen to be quite mobile: it gives the carbon signal near 0 ppm, and the proton signal for this site is very sharp, indicating significant motional narrowing. The PS peaks, on the other hand, give very broad proton resonances, showing that the PS part of this block copolymer is essentially static at this temperature. With this experiment, quick qualitative assessments of relative local mobility in organic solids and polymers can be made. Figure adapted from Schmidt-Rohr K and Spiess HW (1994) *Multidimensional Solid-State NMR and Polymers*. London: Academic Press.

signal is observed only after the nuclear magnetization has been perturbed from its equilibrium state, relaxation is a standard feature of all NMR experiments. Two primary relaxation processes are usually identifiable. The first is the relaxation of the total magnetization back to its thermal equilibrium value; this occurs on a timescale denoted T_1 . The second is the timescale for relaxation of quantum coherences in the spins, and is denoted T_2 . In liquids, due to the strong decoupling resulting from the molecular motion, these two processes occur on similar timescales. In solids, however, they are usually very different, with T_2 ranging typically from 10^{-4} to 10^{-2} s, and T_1 from 10^{-3} to 10^3 s. Relaxation occurs because fluctuations in the surroundings of a spin induce transitions within the spin quantum states. Therefore, measurements of relaxation times are indirect probes of the dynamics in the solid. However, identifying what sort of fluctuation is operative is usually very difficult, unless one type of interaction is clearly dominant (conduction electrons in a metal or superconductor is a good example). Otherwise, the best that can be done is to estimate the temperature and magnetic field dependence of the relaxation to be expected from candidate fluctuation modes, and to compare the predictions with the data.

An easier qualitative assessment of dynamics can often be obtained from resonance line shapes. As noted above, the key distinction between solid-like and liquid-like NMR spectra is the timescale of the atomic motions, compared to the frequency spread of the detected interactions. As the rate of a dynamic process increases, say as a function of

temperature, it can be followed through changes in the line widths of the nuclei involved. These changes can be substantial, as a resonance goes from solid-like at low temperatures to liquid-like at high temperatures, with the line width decreasing by orders of magnitude.

The line width strategy is particularly effective if no additional line-narrowing is needed to interpret the low-temperature spectra; however, it is often the case that these spectra will be so congested that additional techniques such as MAS must be applied. In that case, the line-narrowing caused by heating the sample is much less dramatic. In this case, two-dimensional spectroscopy can again be very helpful. For organic solids and polymers, the wideline separation of interactions (WISE) experiment is a convenient qualitative measure of the relative site dynamics. This experiment combines the good resolution found in ^{13}C spectra under MAS, with the strong internuclear coupling of protons. The latter feature makes proton spectra particularly good indicators of motional narrowing due to dynamics: broad proton resonances (30–50 kHz) are seen in static samples, and narrow (<1 kHz) for mobile sites. The WISE experiment works by adding an additional evolution time to the CP-MAS sequence, between the proton excitation and the contact pulse to the carbons, and using relatively slow sample spinning. In this way, a two-dimensional spectrum is obtained, with proton resonances sorted by the carbon sites to which they are bonded (**Figure 6**). One can immediately see, therefore, which carbon sites are mobile (narrow associated proton resonances) and which are static (broad proton resonances).

Figure 7 Two-dimensional ^2H exchange spectrum of deuterated dimethylsulfoxone. The strong diagonal ridge reflects molecules that have not reoriented during the mixing time, while the pattern of ellipses off the diagonal shows those that have. The ellipses arise due to the orientational dependence of the ^2H quadrupole interaction, the dominant anisotropy here. The distribution of jump angles is shown on the right, and sharply peaked at zero (static molecules) and 72° , the included angle of the C–D bonds as the entire molecule executes hops about its symmetry axis. With this type of experiment, slow to moderate dynamics of molecules and polymers can be followed in atomic-level detail. Figure adapted from Schmidt-Rohr K and Spiess HW (1994) *Multidimensional Solid-State NMR and Polymers*. London: Academic Press.

More detailed information on dynamics is available from so-called exchange experiments. This class of two-dimensional technique provides a correlation between spectral components, which exchange during a mixing period. The exchange may occur because of a chemical transformation during the mixing time, resulting in a new frequency due to a new chemical environment, or because of site reorientation. Since the nuclear spin interactions are orientation-dependent, if the molecular unit changes its orientation during the mixing time, the involved nuclear spins will exhibit altered NMR frequencies, which can be correlated to their initial values. Because the orientation dependences of NMR interactions are well known, it is often a straightforward matter to relate the observed exchange spectrum to the underlying molecular motion that gave rise to it. In this way, very detailed information on microscopic molecular dynamics can be obtained.

Deuterium NMR spectra provide particularly clear examples of the above approach. For the deuterium nucleus, the quadrupole interaction is dominant, by far and in a C–D bond, is aligned with the C–D bond itself. Therefore, changes in time of the deuterium quadrupole orientation give a direct reflection of the orientational dynamics of the C–D bond itself. **Figure 7** shows the two-dimensional exchange spectrum of deuterated dimethyl sulfone ((CD₃)₂SO₂). The strong diagonal ridge is a typical deuterium NMR spectrum, and arises from molecules that did not exchange during the mixing time. The pattern of ellipses off the diagonal arises due to deuterium nuclei with one orientation, and hence one frequency, at the start of the experiment, and a second orientation, hence frequency, after the mixing time. This pattern is consistent with 180° jumps of the molecules about their symmetry axis. The exchange experiment can be applied to other nuclei as well, such as ¹³C, although it can be harder to relate the spin interaction orientation to a molecular frame of reference.

Summary

In this article we have attempted to provide a brief overview of modern techniques and their applications in

solid state NMR. Far from being exhaustive, we hope instead to have informed the reader about the types of problems that can be investigated fruitfully with this approach, using what have become standard methods. There are many other more specialized techniques, suitable for particular problems, which are described in the current literature. The following bibliography is meant to provide a starting point for newcomers to the field. The 'Further Reading' section provides entry into the technical primary literature.

Symbols

$A_d(t)$	spatial dependence of the dipolar Hamiltonian
B_0	external applied magnetic field
d_m	Fourier components of the dipole–dipole coupling
h	Planck constant
$\hbar$	Planck constant divided by 2π
$\hat{\mathcal{H}}_{DD}$	average dipolar Hamiltonian
$\mathcal{H}_{DD}$	direct dipolar Hamiltonian operator
$\mathcal{H}_J$	indirect spin–spin coupling Hamiltonian
$\mathcal{H}_{Z,CS}$	chemical shielding perturbed Zeeman Hamiltonian operator
$\hat{I}_-$	lowering operator
$\hat{I}_+$	raising operator
$\hat{I}_i$	spin angular momentum operator for spin i
$\hat{I}_{zi}$	z -component of the spin angular momentum operator for spin i
J	indirect spin–spin coupling constant
n	order of the rotational resonance
r_{12}	distance between spins 1 and 2; internuclear vector
R_{DD}	direct dipolar coupling constant (in Hz)
R_{eff}	observed dipolar coupling constant
t	time
T_{20}	spin term in the spherical tensor representation of the dipolar Hamiltonian
T_2^{ZQ}	zero-quantum relaxation time constant
U	propagator
γ_i	magnetogyric ratio of spin i
ΔJ	anisotropy of the indirect spin–spin interaction
θ	angle between the applied field and the internuclear vector
Λ^2	dephasing parameter
μ_0	permeability of free space
ν_r	rotor frequency in Hz
$\nu_i, \nu_i^{\text{iso}}$	isotropic resonant frequency of nucleus i (in Hz)
ν_{rot}	rotor frequency (in Hz)
$\nu_{1/2}$	line width at half-height (in Hz)
$\xi(t)$	time-dependence of the NMR interactions as a result of sample rotation
σ_i	chemical shielding tensor of spin i
σ_{ii}	principal component of the chemical shielding tensor ($i = 1, 2, 3$)

σ^{iso}	isotropic chemical shielding constant
τ_m	variable mixing time
$\omega_B^{(n)}$	resonant Fourier components
ω_i	CS-perturbed Zeeman angular frequency of spin i (in rad s^{-1})
ω_r	rotor frequency (in rad s^{-1})
$\omega_{\Delta}^{\text{iso}}$	difference in isotropic angular frequencies of spins 1 and 2.

Introduction

One of the primary goals of solid-state NMR spectroscopists has been to develop techniques that yield NMR spectra of solid samples with resolution approaching that observed for samples in isotropic liquids. Rapidly spinning samples about an axis inclined at the magic angle ($\arccos(1/\sqrt{3}) = 54.7356^\circ$) relative to the applied static magnetic field has been found to be highly effective in this regard. In addition, high-power decoupling of abundant spins (e.g. ^1H) eliminates heteronuclear spin–spin coupling interactions (direct dipolar and indirect J -coupling) involving the abundant spins when dilute spins are examined. The availability of commercial NMR instrumentation that permits users to apply these two techniques has contributed to spin- $\frac{1}{2}$ NMR becoming a routine method for examining a wide range of solid materials. Finally, cross-polarization (CP) from abundant spins to dilute spins has been important in improving the sensitivity of the dilute-spin NMR experiment.

Ironically, it is sometimes desirable to selectively reintroduce interactions which are effectively averaged in the magic-angle-spinning (MAS) experiment. Dipolar coupling, for instance, may be recovered in the form of the direct dipolar coupling constant (R_{DD}) between isolated spin pairs. The value of R_{DD} is of interest due to its simple relationship with the distance separating two spins, r_{12} (eqn [1])

$$R_{DD} = \frac{\mu_0}{4\pi} \frac{\gamma_1 \gamma_2}{\langle r_{12}^3 \rangle} \frac{\hbar}{2\pi} \quad [1]$$

where μ_0 is the permeability of free space, and γ_i are the magnetogyric ratios of the nuclei under consideration.

Rotational resonance (RR) is a MAS NMR technique which selectively restores the dipolar interaction between a homonuclear spin pair, thus allowing the determination of the dipolar coupling constant, R_{DD} , and hence, the internuclear distance. Historically, the RR phenomenon was discovered by Andrew and co-workers in a ^{31}P NMR study of phosphorus pentachloride, which consists of PCl_4^+ and PCl_6^- units in the solid state. This group noticed that when the rate of sample spinning matched the difference in resonance frequencies of the nonequivalent phosphorus centres, their peaks broadened and the rate of cross-relaxation was enhanced.

It is now known that if the RR condition is satisfied, direct dipolar coupling is restored selectively to a homonuclear spin pair. That is, if the sample spinning rate is adjusted to a frequency, ν_r , such that

$$n\nu_r = (\nu_1^{\text{iso}} - \nu_2^{\text{iso}}) \quad [2]$$

where n is an integer, generally 1–3, and ν_1^{iso} and ν_2^{iso} are the isotropic resonant frequencies of spins 1 and 2 respectively, then the two nuclei are said to be in RR. As a result, dipolar coupling between the nuclei is restored (via the ‘flip-flop’ term in the dipolar Hamiltonian), and ‘line broadening’ of the resonances at ν_1^{iso} and ν_2^{iso} is observed (see **Figure 1**). Additionally, a rapid oscillatory exchange of Zeeman magnetization occurs. In fact, it is this exchange of magnetization rather than the lineshape which is usually monitored in order to determine the dipolar coupling constant. In order to generate an exchange curve which may be analysed and simulated, one of the two resonances involved must be inverted selectively; the intensity difference of the peaks is then monitored as function of time.

Figure 1 Effect of RR on the ^{13}C NMR lineshape of $\text{Ph}^{13}\text{CH}_2^{13}\text{COOH}$. Spectra acquired at 4.7 T (50.3 MHz). Top spectrum at $n = 1$ RR, $\nu_{\text{rot}} = 7207$ Hz. Bottom spectrum off RR, $\nu_{\text{rot}} = 10\,000$ Hz.

Obviously, it is highly desirable to develop techniques capable of recovering weak dipolar coupling constants from high-resolution NMR spectra obtained under MAS conditions. The focus of the present discussion will be to provide an overview of the basic RR scheme. First, the theory of RR will be outlined, followed by a discussion of the most important experimental techniques employed to measure dipolar coupling constants under conditions of RR. Finally, some examples that illustrate the applications and limitation of the techniques will be described.

Theory

Restoring the Dipolar Interaction: A Theoretical Approach

The most important interaction in NMR results from the application of a large external magnetic field, B_0 , to the sample. Termed the Zeeman interaction, its effect on the normally degenerate nuclear spin energy levels is to cause them to split. The Zeeman levels are perturbed by local fields generated by the motion of electrons in the vicinity of the nucleus. These induced local fields are proportional to the applied field. In frequency units, the Hamiltonian operator which accounts for both the Zeeman interaction and this chemical shielding (CS) interaction is

$$h^{-1} \hat{\mathcal{H}}_{Z, \text{CS}} = - \sum_i \nu_i \hat{I}_{zi} \quad [3]$$

where

$$\nu_i = \frac{\gamma_i B_0 (1 - \sigma_i^{\text{iso}})}{2\pi} \quad [4]$$

and σ_i^{iso} is the isotropic chemical shielding constant.

The interaction of interest in RR is the dipolar interaction, an orientationally dependent through-space spin-spin coupling, which leads to a perturbation of the CS-perturbed Zeeman energy levels. For a homonuclear two-spin system, the truncated dipolar Hamiltonian operator is given by the following:

$$\begin{aligned} h^{-1} \hat{\mathcal{H}}_{\text{DD}} = & - \left(\frac{\mu_0}{4\pi} \right) \gamma^2 \hbar \langle r_{12}^{-3} \rangle \\ & \times \left[\hat{I}_{z1} \hat{I}_{z2} - \frac{1}{4} (\hat{I}_1 + \hat{I}_2)_- + \hat{I}_1 - \hat{I}_2 \right] \\ & \times (3 \cos^2 \theta - 1) \end{aligned} \quad [5]$$

Here, $\hat{I}_+$ and $\hat{I}_-$ are the raising and lowering operators and θ is the angle between the applied magnetic field and the internuclear vector, r_{12} . The factor containing the raising and lowering operators is sometimes referred to as the ‘flip-flop’ term.

The final interaction that must be considered is the indirect spin–spin coupling interaction, which is mediated by the intervening electrons. The indirect spin–spin Hamiltonian, $\mathcal{H}_J$, is often ignored because it is frequently considerably smaller than $\mathcal{H}_{DD}$.

Up until this point, we have implicitly assumed time independence of the interactions and their corresponding Hamiltonian operators. This assumption is valid for a rigid stationary sample. However, when the sample is spun rapidly, each of the internal Hamiltonians becomes time-dependent. For example, $\mathcal{H}_{Z,CS}$ becomes time-dependent when there is chemical shielding anisotropy due to the fact that the orientations of the chemical shielding tensors relative to the applied magnetic field change as the sample rotates. Then eqn [3] becomes

$$\hbar^{-1} \mathcal{H}_{Z,CS}(t) = -\sum_i \gamma_i B_0 [(1 - \sigma_i^{\text{iso}}) + (\sigma_{i,zz} - \sigma_i^{\text{iso}}) \zeta(t)] \hat{I}_{zi} \quad [6]$$

where $(\sigma_{i,zz} - \sigma_i^{\text{iso}})$ is a measure of the orientation dependence of the chemical shielding and $\zeta(t)$ represents the time dependence of the interaction:

$$\zeta(t) = C_1 \cos(\omega_r t) + S_1 \sin(\omega_r t) + C_2 \cos(2\omega_r t) + S_2 \sin(2\omega_r t) \quad [7]$$

Here, C_1 , C_2 , S_1 , and S_2 are constants that depend on the nature of the interaction (i.e. CS, dipolar) and ω_r is the rotor angular frequency.

Summing the CS-perturbed Zeeman Hamiltonian given in eqn [6] with the time-dependent dipolar Hamiltonian gives the total Hamiltonian

$$\begin{aligned} \hbar^{-1} \mathcal{H}(t) = & -\sum_i \gamma_i B_0 [(1 - \sigma_i^{\text{iso}}) + (\sigma_{i,zz} - \sigma_i^{\text{iso}}) \zeta(t)] \hat{I}_{zi} \\ & - \left(\frac{\mu_0}{4\pi} \right) \gamma^2 \hbar \langle r_{12}^{-3} \rangle \\ & \times \zeta(t) \left[\hat{I}_{z1} \hat{I}_{z2} - \frac{1}{4} (\hat{I}_{1+} \hat{I}_{2-} + \hat{I}_{1-} \hat{I}_{2+}) \right] \end{aligned} \quad [8]$$

The parameter $\zeta(t)$ completely describes the time-dependence of a rotating solid.

In order to understand some of the essential features of the RR experiment, it is convenient to assume negligible chemical shielding anisotropy. Under these conditions, ω_1 and ω_2 , the CS-perturbed Zeeman angular frequencies, are independent of time. In addition, it is convenient to use the spherical tensor notation to describe the direct dipolar interaction. Thus, the total Hamiltonian is

$$\hbar^{-1} \mathcal{H}(t) = \omega_1 \hat{I}_{z1} + \omega_2 \hat{I}_{z2} + A_d(t) T_{20} \quad [9]$$

where

$$A_d(t) = -\sqrt{6}(2\pi R_{DD}) \sum_{m=-2}^2 d_m \exp(-i m \omega_r t) \quad [10]$$

Here, $A_d(t)$ represents the spatial dependence of the dipolar Hamiltonian, and d_m are Fourier components of the dipole–dipole coupling which depend on Euler angles defining the crystallite orientation with respect to the rotor frame. They are time-independent. The spin part of the truncated dipolar Hamiltonian is

$$T_{20} = \frac{2}{\sqrt{6}} \left[\hat{I}_{z1} \hat{I}_{z2} - \frac{1}{4} (\hat{I}_{1+} \hat{I}_{2-} + \hat{I}_{1-} \hat{I}_{2+}) \right] \quad [11]$$

To transform the total Hamiltonian into the doubly rotating frame of reference defined by the Zeeman interactions, the propagator is

$$U^{\text{int}} = \exp[i(\omega_1 \hat{I}_{z1} + \omega_2 \hat{I}_{z2})t] \quad [12]$$

The Zeeman terms and the $\hat{I}_z$ terms of the dipolar Hamiltonian are unaffected by this rotation since it is about the z -axis, and so the desired transformation is:

$$T_{20}^{\text{int}} = (U^{\text{int}}) T_{20} (U^{\text{int}})^{-1} \quad [13]$$

The result of the transformation gives a periodic interaction frame dipolar Hamiltonian,

$$\begin{aligned} \hbar^{-1} \mathcal{H}_{DD}^{\text{int}}(t) = & -2(2\pi R_{DD}) \sum_m z d_m \left(\hat{I}_{z1} \hat{I}_{z2} \exp(-i m \omega_r t) \right. \\ & \left. - \frac{1}{4} \left\{ \begin{aligned} & \hat{I}_{1+} \hat{I}_{2-} \exp[i(\omega_{\Delta}^{\text{iso}} - m \omega_r t)] \\ & + \hat{I}_{1-} \hat{I}_{2+} \exp[-i(\omega_{\Delta}^{\text{iso}} + m \omega_r t)] \end{aligned} \right\} \right) \end{aligned} \quad [14]$$

where $\omega_{\Delta}^{\text{iso}} = \omega_1 - \omega_2$. If we re-express the rotational resonance condition [2] in angular frequency units as $n\omega_r = \omega_{\Delta}^{\text{iso}}$, and if $|R_{DD}\tau_r| \ll 1$, where $\tau_r = \nu_r^{-1}$ is the rotor period, then the time-independent terms vanish and the time average of eqn [14] over one rotor period is

$$\overline{\hbar^{-1} \mathcal{H}_{DD}^{\text{int}}} = \frac{1}{2} (2\pi R_{DD}) (d_m \hat{I}_{1+} \hat{I}_{2-} + d_{-m} \hat{I}_{1-} \hat{I}_{2+}) \quad [15]$$

where $m = \pm 1, \pm 2$. The result of this exercise is that at rotational resonance, parts of the ‘flip-flop’ term do not average to zero and will therefore contribute to the MAS NMR spectrum.

Some qualitative results of an approximate theoretical treatment of rotational resonance are useful to examine. For $n = 1$ RR, the splitting of each peak is given by $R_{DD}/(2\sqrt{2})$, or $\sim 0.35 R_{DD}$. For the $n = 2$ case, the splitting is $R_{DD}/4$. The splitting decreases as the order of the RR increases. More rigorous treatments also indicate that the

splitting decreases as the chemical shielding anisotropy increases. It is important to note that the observed line widths for homonuclear spin systems are not strictly independent of spinning speed; for a spin pair with differing isotropic chemical shifts, the line widths take on a ω_r^{-2} dependence at high spinning speeds.

When the RR condition is satisfied, a rapid exchange of Zeeman magnetization occurs in addition to dipolar broadening. We will not present a complete theoretical description of the origins of this exchange, but rather present some of the important approximate results of such a treatment. It is convenient to define

$$\Lambda^2 = \left(T_2^{ZQ}\right)^{-2} - 4\left|\overline{\omega_B^{(n)}}\right|^2 \quad [16]$$

where T_2^{ZQ} is the zero-quantum relaxation time constant, and $\overline{\omega_B^{(n)}}$ are the resonant Fourier components associated with the flip-flop term of the dipolar Hamiltonian for RR of order n . To monitor the exchange of magnetization, one plots $\langle \hat{I}_{z1} - \hat{I}_{z2} \rangle$ as a function of time. In the limit of very fast dephasing where T_2^{ZQ} is relatively short and thus $\Lambda^2 \gg 0$, the decay of magnetization is exponential:

$$\langle \hat{I}_{z1} - \hat{I}_{z2} \rangle(t) \approx \exp\left(-T_2^{ZQ}\left|\overline{\omega_B^{(n)}}\right|^2 t\right) \quad [17]$$

In the case of very slow dephasing where T_2^{ZQ} is relatively long and $\Lambda^2 \ll 0$, the exchange of magnetization oscillates as it decays:

$$\langle \hat{I}_{z1} - \hat{I}_{z2} \rangle(t) \approx \exp\left(-\frac{t}{2T_2^{ZQ}}\right) \cos\left(\left|\overline{\omega_B^{(n)}}\right| t\right) \quad [18]$$

In practice, the parameters which influence the observed magnetization exchange curve include R_{DD} , T_2^{ZQ} , the magnitude of the principal components of the chemical shielding tensors, the relative orientation of the CS tensors with respect to r_{12} , and the J -coupling constant.

A Pictorial Representation of Rotational Resonance and the Exchange of Zeeman Magnetization

At this point, it is instructive to provide a qualitative picture of the rotational resonance phenomenon. The energy level diagram for an isolated homonuclear two-spin system where the two nuclei have resonance frequencies ν_1^{iso} and ν_2^{iso} is shown in **Figure 2**. Transitions 1 and 2 correspond to the two isotropic peaks, which would be observed in a MAS NMR spectrum. The difference between the isotropic chemical shifts (or, alternatively, the energies) is, according to

Figure 2 Simplified energy level diagram for two spin- $\frac{1}{2}$ nuclei with different isotropic chemical shifts. The two transitions are labelled '1' and '2', and their difference is greatly exaggerated. The energy of the zero-quantum transition is indicated, which corresponds to the mechanical energy supplied at RR. Here, J -coupling is ignored and dipolar coupling is not shown.

Figure 3 Energy level and population distribution diagrams for two spin- $\frac{1}{2}$ nuclei. The circles indicate the excess population in arbitrary units relative to the least populated level. On the left, an equilibrium Boltzmann-type distribution is represented. Both transitions would show a signal of relative intensity +2. Upon inversion of transition 1 (at right) the populations related to this transition are switched, while the net difference in population for transition 2 is unchanged. Transition 1 would now show an inverted signal with relative intensity -2.

the diagram, equivalent to the angular frequency $\omega_{\Delta}^{\text{iso}}$. As shown earlier, rotational resonance occurs when an integer multiple of the spinning frequency is equivalent to $\omega_{\Delta}^{\text{iso}}$. In terms of the diagram, it is convenient to think of the mechanical rotation of the sample as supplying the necessary energy for zero-quantum coherence between the two intermediate energy levels. The fact that these two states are linked by mechanical rotation ensures that the dipolar interaction will be recoupled, and that exchange of Zeeman magnetization will occur rapidly.

Figure 3 illustrates the exchange experiment, in which one of the transitions is selectively inverted, thus creating a nonequilibrium situation in which spins must relax so that the equilibrium Boltzmann populations are re-established. If we consider the diagram on the left to reflect the excess populations in arbitrary units as determined by the Boltzmann distribution, a selective

inversion of transition 1 will result in the population distribution shown on the right. Transition 1 is inverted while the intensity of transition 2 remains unperturbed. Techniques for accomplishing this experimentally will be discussed in the next section. Once the inversion has been carried out, the diagram on the right shows a difference of five population units between the two intermediate energy levels. Rotational resonance provides the zero-quantum coherence necessary for an exchange of Zeeman magnetization between these two levels. The zero-quantum relaxation which dampens this exchange is described by the time constant T_2^{ZQ} .

Experimental Techniques

Pulse Sequences and Cross-Polarization

The basic rotational resonance experiment can be as simple a single-pulse excitation, with the rate of MAS adjusted to satisfy the RR condition. A $\pi/2$ pulse followed by acquisition of the free induction decay (FID) will generate a spectrum with significant broadening of the two resonances concerned. Many typical applications involve ^{13}C in the presence of ^1H , and benefit from standard CP techniques. **Figure 1** shows an example of the line broadening observed for the $n = 1$ RR condition for the ^{13}C – ^{13}C spin pair in $\text{Ph}^{13}\text{CH}_2^{13}\text{COOH}$, with CP.

A typical pulse sequence for carrying out the RR experiment with selective inversion of a particular transition and CP is shown in **Figure 4**. Note that a flipback pulse is applied to the rare spin channel to store the magnetization along the z axis before carrying out the inversion. The efficiency of CP becomes sensitive to the spinning rate, particularly as ω_r increases. One technique which attempts to circumvent this problem is known as variable amplitude cross-polarization (VACP), where the spin-locking pulses vary in amplitude.

The goal of the RR experiment is the extraction of the homonuclear dipolar coupling constant, R_{DD} . This can be done by carrying out lineshape simulations.

Figure 4 Pulse sequence for carrying out the RR experiment (see text). In the case of the magnetization exchange experiment, CP of the rare spins is followed by a flipback pulse on the rare spin channel, selective inversion of a particular resonance, and a variable delay before acquisition.

However, in general this is not done because a Zeeman magnetization exchange experiment is more informative, and more sensitive to the magnitude of R_{DD} , as will be shown.

The Exchange Experiment

To generate an exchange curve, one of the two resonances involved must be inverted selectively. By whichever technique a selective inversion is carried out, it is important that the other resonances not be perturbed. The most frequently used inversion techniques in RR experiments are a long, soft pulse or an asynchronous DANTE (delays alternating with nutation for tailored excitation) sequence.

In cases where the CS anisotropy at one or both of the sites is comparable to the isotropic chemical shift difference between them, difficulties arise in carrying out the inversion with selectivity. Total sideband suppression pulse sequences combined with their time-reversed counterparts may be used to overcome the difficulties associated with large chemical shift anisotropies. Regardless of what technique is used to establish the initial condition of maximum polarization difference, the next step in the experiment is to allow the exchange of Zeeman magnetization for a variable time, τ_m (see **Figure 4**), before applying a $\pi/2$ acquisition pulse. The equilibration of magnetization between the two sets of spins is described by the approximate eqn [17] or [18], depending on the system.

Applications and Limitations

As mentioned previously, the primary goal of the rotational resonance experiment is to determine the dipolar coupling constant, R_{DD} , from which the internuclear distance, r , may be calculated. Carbon–carbon separations as large as $6.8 \text{ \AA}$ have been successfully determined, which corresponds to measuring a coupling as small as 24 Hz. Occasionally, dihedral angle measurements have also been carried out using RR. At higher order rotational resonances (i.e. $n = 3$ or $n = 4$), where CS anisotropy is more likely to be comparable to ν_r , the lineshapes and exchange curves are more sensitive to the orientation of the chemical shielding tensors. In general, when simulations (of either lineshapes or exchange curves) are performed, they depend on R_{DD} and, to varying degrees, on the magnitudes of the principal components of the chemical shielding tensors, their orientations with respect to the internuclear vector and with respect to each other, the magnitude of the J -coupling, and the zero-quantum transverse relaxation time constant, T_2^{ZQ} .

Lineshape Simulations

In order to effectively determine a dipolar coupling constant based on a lineshape simulation, the chemical shielding tensors and their orientations must be known, as well as the J -coupling constant, and T_2^{ZQ} . To determine the principal components of the chemical shielding tensors, a MAS NMR spectrum acquired on a singly labelled compound in the slow-spinning regime may be used to emulate the powder pattern provided the isolated spin approximation is valid. In some cases it is also possible to determine the CS tensor components from a spectrum of the stationary sample. Determining the *orientations* of the CS tensors is a more involved process, although in some cases careful assumptions and clues from local symmetry may be helpful. In practice, a value for T_2^{ZQ} is usually estimated from the observed line widths off the RR condition.

$$(T_2^{ZQ})^{-1} = \pi[v_{1/2}(1) + v_{1/2}(2)] \quad [19]$$

In many cases, not all these parameters are known for the specific spin system under investigation. Therefore, two techniques that may be employed when a lineshape simulation is desirable are (i) a simulation based on known chemical shielding tensors (σ), J -coupling constants, and T_2^{ZQ} values, where only R_{DD} is varied; (ii) use of a calibration with respect to similar compounds, where R_{DD} (or r itself) can be extracted analytically from the observed splitting of a resonance.

For example, the calibration method (ii) has been employed for a series of ^{13}C -labelled retinals containing vinylic and methyl carbons, shown in **Figure 5**. The three isotopomers were ^{13}C -labelled at the (10, 20), (11, 20), and (12, 20) positions. It must be emphasized that the required parameters (σ , J , T_2^{ZQ} and r) were known independently from X-ray and previous NMR studies. T_2^{ZQ} was estimated using eqn [19]. The goal of the calibration was to be able to employ a simple, analytic equation relating r to the observed broadening of the vinylic peaks at RR. To accomplish this, the 'ideal' splitting presented above, $R_{DD}/(2\sqrt{2})$, was plotted against

Figure 5 Structure of the retinal studied using RR, with the labelled carbons indicated. See text for details. Reprinted with permission of the American Chemical Society from Verdegem PJE, Helmle M, Lugtenburg J, and de Groot HJM (1997) *Journal of the American Chemical Society* 119: 169–174.

the observed splitting, $\Delta\omega$. Simulations showed that $\Delta\omega$ could be reliably reproduced, independent of the actual shape of the line. The resulting equation,

$$\frac{R_{DD}}{\sqrt{8}} = 1.15 \left(\frac{\Delta\omega}{2\pi} \right) + 7 \text{ (Hz)} \quad [20]$$

shows that the approximate theory fits well with experimental results in this case, and allows for a very straightforward determination of r from the observed splitting. The major advantage of using lineshape simulations to extract the dipolar coupling constant, in general, is that the spectrometer time involved is less than that for the corresponding magnetization exchange experiment. For molecules similar to the retinal in **Figure 5**, where r is unknown, the analytical empirical eqn [20] can provide the information after a simple 1D NMR experiment.

In spite of the results of the preceding example, the lineshape simulation method has rarely been used in practice, mainly because the R_{DD} values are too small to result in splittings. In such cases, the exchange curve method discussed below is the standard technique for extracting the dipolar coupling constant under RR conditions.

Exchange Curves and Simulations

By far the most common method for deriving structural information under RR conditions is through the analysis and simulation of a magnetization exchange curve. Once a suitable state of polarization difference has been achieved between the two sets of spins, 1 and 2, the delay time, τ_m , is varied before applying a $\pi/2$ observe pulse and acquiring the spectrum (see **Figure 4**). Separate NMR experiments must be performed to generate each point on a magnetization exchange plot.

In order to extract the dipolar coupling constant or structural information, the observed magnetization decay must be simulated. Qualitative and relative distance information is more readily available than quantitative information since the exchange curve depends on the same parameters that the RR lineshape depends on. Two common procedures for extracting R_{eff} are (i) comparison of the exchange curve with a series of exchange curves of model compounds for which r is known, and (ii) complete simulation of the exchange curve, where σ , J , and T_2^{ZQ} are known (or estimated).

The magnetization due to naturally abundant NMR-active spins in the sample must be considered. This is done by subtracting the natural-abundance spectrum from that of the labelled sample. Failure to make such a correction could lead to an overestimation of r and an underestimation of T_2^{ZQ} .

An example of the application of RR to a structural problem will serve to illustrate its utility as a comparative

Figure 6 Fragments of the peptide β 34-42 showing the *cis* and *trans* conformations. Also indicated is the orientation of the carbonyl carbon chemical shielding tensor, with σ_{33} perpendicular to the plane. Note the different orientations of the C–C internuclear vector with respect to the CS tensor components. tool. **Figure 6** shows two peptide fragments in different conformations. This compound models the peptide A β 1-42, a constituent of the amyloid plaques characteristic of Alzheimer's disease. Rotational resonance MAS NMR was used in a qualitative fashion by Costa and co-workers to determine whether the amide conformation in the solid state was '*cis*' or '*trans*'. From previous experiments, model compounds served to give the chemical shielding tensor orientations of the carbonyl carbon. The orientation of the internuclear vector connecting the two labelled carbon atoms with respect to the chemical shielding tensor of the carbonyl carbon is drastically different for the two conformers shown in **Figure 6**. Note that in the *trans* conformation, the internuclear vector lies nearly along the σ_{11} component, while in the *cis* conformation it lies nearly along σ_{22} . The dipolar coupling for the two conformations should, however, be nearly identical. Hence, the variable of interest in this experiment is the CS tensor orientation. Experimental Zeeman magnetization exchange curves were generated and matched to simulated curves (**Figure 7**). It was found that theory matched experiment only when a *trans* geometry was assumed. The $n = 2$ RR experiment was used in this case because at higher spinning speed (i.e. $n = 1$), the orientations of the CS tensors become less influential in determining the course of the magnetization exchange.

This example shows that RR experiments can be used for more than simply extracting the dipolar coupling constant and determining an accurate value for r_{12} . In fact, the basic RR technique is probably better suited to

Figure 7 Zeeman magnetization exchange plot for the peptide β 34-42 fragments shown in **Figure 6**. qualitative distance measurements such as in the example given.

It is necessary to make a general comment regarding the influence of molecular motion on the measurement of dipolar coupling constants. In the context of solid-state NMR, it is not r_{12} which is directly measured, but rather the dipolar coupling constant. Molecular librations and vibrations will cause a certain degree of averaging of the dipolar interaction and thus R_{DD} . The net result of the motional averaging of the dipolar coupling is that the calculated distances, r , will be too large.

Finally, it is important to recognize that the dipolar coupling constant measured in any NMR experiment also has, in principle, a contribution from the anisotropy in the indirect spin–spin coupling, ΔJ . That is, only an effective dipolar coupling constant, R_{eff} , can be measured where

$$R_{\text{eff}} = R_{DD} - \Delta J/3 \quad [21]$$

The last term in eqn [21], $\Delta J/3$, is generally ignored.

Other Homonuclear Recoupling Methods

Restoring the dipolar coupling between both heteronuclear and homonuclear spin pairs is of great interest.

Table 1 A summary of some homonuclear dipolar recoupling techniques

Name	Acronym	Principle
Rotational resonance	RR	Recouples when the difference in chemical shift frequencies is an integer multiple of the MAS speed.
Dipolar recovery at the magic angle	DRAMA	In its simplest form, a pair of x and $-x$ π pulses separated by a delay, τ , results in an observable dipolar broadening (Tycko R and Dabbagh G (1991) Double-quantum filtering in magic-angle-spinning NMR spectroscopy: An approach to spectral simplification and molecular structure determination. <i>Journal of the American Chemical Society</i> 113: 9444–9448).
Simple excitation for the dephasing of the rotational-echo amplitudes	SEDRA	Synchronously applied pulses lead to signal dephasing for dipolar coupled spins (Gullion T and Vega S (1992) A simple magic angle spinning NMR experiment for the dephasing of rotational echoes of dipolar coupled homonuclear spin pairs. <i>Chemical Physics Letters</i> 194: 423–428).
Radio frequency driven dipolar recoupling	RFDR	Rotor-synchronized π -pulses reintroduces flip-flop term (Bennett AE, Ok JH, Griffin RG, and Vega S (1992) Chemical shift correlation spectroscopy in rotating solids: Radio frequency-driven dipolar recoupling and longitudinal exchange. <i>Journal of Chemical Physics</i> 96: 8624–8627).
Unified spin echo and magic echo	USEME	Spin-echo and magic-echo sequences are applied to recover the dipolar interaction (Fujiwara T, Ramamoorthy A, Nagayama K, Hioka K, and Fujito T (1993) Dipolar HOHAHA under MAS conditions for solid-state NMR. <i>Chemical Physics Letters</i> 212: 81–84).
Combines rotation with nutation	CROWN	Dipolar dephasing occurs due to applied RF pulses (Joers JM, Rosanske R, Gullion T, and Garbow JR (1994) Detection of dipolar interactions by CROWN NMR. <i>Journal of Magnetic Resonance</i> A106: 123–126).
Double quantum homo-nuclear rotary resonance	2Q1-HORROR	RF field applied at half the rotation frequency in conjunction with RF pulses (Nielsen NC, Bildsøe H, Jakobsen HJ, and Levitt MH (1994) Double-quantum homonuclear rotary resonance: Efficient dipolar recovery in magic-angle-spinning nuclear magnetic resonance. <i>Journal of Chemical Physics</i> 101(3): 1805–1812).
Melding of spin-locking dipolar recovery at the magic angle	MELODRAMA	Rotor-synchronized 90° phase shifts of the applied spin-locking field (Sun B-Q, Costa PR, Kocisko D, Lansbury PT Jr, and Griffin RG (1995) Internuclear distance measurements in solid state nuclear magnetic resonance: Dipolar recoupling via rotor synchronized spin locking. <i>Journal of Chemical Physics</i> 102: 702–707).
Rotational resonance in the tilted rotating frame	R2TR	Application of an RF field allows selective recoupling when the chemical shift difference is small (Takegoshi K, Nomura K, and Terao T (1995) Rotational resonance in the tilted rotating frame. <i>Chemical Physics Letters</i> 232: 424–428).
Sevenfold symmetric radio-frequency pulse sequence	C7	Seven phase-shifted RF pulse cycles lead to dipolar recoupling (Lee YK, Kurur ND, Helmle M, Johannessen OG, Nielsen NC, and Levitt MH (1995) Efficient dipolar recoupling in the NMR of rotating solids. A sevenfold symmetric radiofrequency pulse sequence. <i>Chemical Physics Letters</i> 242: 304–309).
Dipolar recoupling with a windowless multipulse irradiation	DRAWS	Windowless DRAMA sequence (Gregory DM, Wolfe GM, Jarvie TP, Sheils JC, and Drobny GP (1996) Double-quantum filtering in magic-angle-spinning NMR spectroscopy applied to DNA oligomers. <i>Molecular Physics</i> 89(6): 1835–1850).
Rotational resonance tickling	R ² T	Ramped RF field during the variable delay removes the T_2^Q dependence (Costa PR, Sun B, and Griffin RG (1997) Rotational resonance tickling: Accurate internuclear distance measurement in solids. <i>Journal of the American Chemical Society</i> 119: 10821–10830).
Adiabatic passage rotational resonance	APRR	MAS speed varied during CP mixing to achieve more complete polarization transfer (Verel R, Baldus M, Nijman M, van Os JWM, and Meier BH (1997) Adiabatic homo-nuclear polarization transfer in magic-angle-spinning solid-state NMR. <i>Chemical Physics Letters</i> 280: 31–39).
Supercycled POST-C5	SPC-5	Fivefold symmetric pulse sequence leads to homonuclear dipolar recoupling (Hohwy M, Rienstra CM, Jaroniec CP, and Griffin RG (1999) Fivefold symmetric homonuclear dipolar recoupling in rotating solids: Application to double quantum spectroscopy. <i>Journal of Chemical Physics</i> 110: 7983–7992).

Rotational resonance applies strictly to homonuclear spin pairs, and **Table 1** provides a brief overview of some of the other techniques available for recovering the dipolar coupling and extracting R_{eff} for homonuclear spin pair from high-resolution MAS spectra.

Conclusions

RR is best suited for use as a qualitative probe into molecular structure rather than a quantitative one. In most experiments which have been done using the basic

RR technique, the internuclear distances were known beforehand as a result of other investigations. Further developments of related RR techniques (such as rotational resonance tickling) may prove to be more useful in obtaining quantitative results. Still, the standard RR experiment is an excellent one for confirming distances between homonuclear spin pairs in a proposed structure.

Introduction

In order to get useful information from NMR spectroscopy of biofluids or biomolecules (proteins, DNA, RNA, carbohydrates, amino acids), it is often necessary to measure ^1H NMR spectra in aqueous solutions. In these samples, the concentration of solvent water protons is about 110 M and is about 10^5 times higher than that of the molecules of interest which are usually in the mM concentration range or less. Such a huge excess of water spins can cause many problems for NMR measurements. Firstly, the receiver gain of the spectrometer must be set to a low value to avoid the water signal overloading the receiver. In this circumstance, the analogue-to-digital converter (ADC) will be filled by the water resonance and many of the small signals from the molecules of interest will be below 1 bit of the ADC resolution and hence will not be digitized adequately. Secondly, the water resonance may obscure many solute peaks, resulting in the loss of molecular structural information that could make the spectrum useless. Thirdly, the strong

water resonance can cause radiation damping, which provides another relaxation mechanism and shortens the relaxation time of water and hence broadens the water peak. Therefore for ^1H NMR spectroscopy to be useful in aqueous solution, it is clearly necessary to attenuate the water signal.

There has been a continued interest in developing new methods for solvent suppression in NMR spectroscopy of biomolecules and biofluids and many methods have been proposed. These fall into five categories: (1) presaturation, (2) nonexcitation, (3) pulsed field gradient (PFG)-based methods, (4) filtering methods and (5) post-acquisition data processing. Among these methods, soft pulse presaturation is the most frequently used and it is also easy to be incorporated into one- (1D) and multidimensional ($n\text{D}$) pulse sequences. The other methods can also be found in some applications, such as the study of exchangeable protons. The use of PFG to enhance the suppression efficiency and to develop new methods has been a popular area of study in NMR spectroscopy. Another advantage of using PFGs is the reduction of radiation damping. The important criteria for a good suppression method are the efficiency, selectivity and phase and baseline properties of the resulting spectrum.

Owing to the limitation of space, this article focuses on the introduction of general principles of the solvent suppression methods, and emphasizes some of the important developments. The reader is encouraged to refer to the original literature and recent reviews for the fundamentals and details of the methods.

Solvent Presaturation

The presaturation method (PR) normally consists of a low-power, soft (long or continuous-wave) pulse at the solvent resonance. It is the simplest and the most widely used method for solvent suppression. The method can be found in a large number of 1D- and $n\text{D}$ -NMR pulse sequences for measuring the ^1H NMR spectra of biofluids or biomolecules in aqueous solutions. The general 1D presaturation pulse sequence is shown in **Figure 1a**, where PR_x is the saturation pulse applied along the x -axis of the rotating frame. The duration of the PR pulse is normally equal to the preacquisition or relaxation

Figure 1 Water suppression pulse sequences, where the bar symbol represents a 90° pulse: (a) presaturation, (b) phase-shifted presaturation (the ratio of the duration of PR_x and PR_y pulses is 9:1), (c) NOESYPRESAT.

delay. It has been found that a long PR pulse with a fixed phase can lock part of the water magnetization along the direction of the RF field. The locked resonance can be reduced by a so-called phase-shifted PR method as shown in **Figure 1b**. The pulse sequence of the phase-shifted presaturation method has two PR pulses with a duration ratio of 9:1 ($PR_x:PR_y$) and a $\pi/2$ phase shift. It had been reported that in conventional 2D COSY [homonuclear chemical shift correlation spectroscopy] and NOESY [2D NOE spectroscopy] experiments on 2 mM lysozyme in a 90% H_2O –10% D_2O solution, a water signal suppression of a factor of 10^6 was achieved using the phase-shift PR method. **Figure 1c** shows a pulse sequence known as NOESYPRESAT, which can be considered as a combination of the phase-shifted PR and conventional NOESY approaches and which can further improve the spectral phasing and baseline. It also provides a more effective suppression in the wide base of the water resonance.

In HPLC–NMR or other applications with solvent mixtures, it is often necessary to suppress two solvent peaks at the same time. This is normally achieved by applying soft pulses or continuous irradiation at both solvent resonances or by fast switching the frequency offset between the two signals. With advances in NMR software, it is now possible to automatically search the solvent frequencies and to define suppression pulse offsets accordingly without any reduction in the suppression efficiency.

The presaturation method can cause a loss of signal intensity of exchangeable protons. This is the result of saturation transfer from the solvent resonance that is

caused by the chemical exchange during the period of the saturation pulse. Generally, care must be taken when using the method to study systems containing labile protons. On the other hand, since the amount of the saturation transfer can be controlled by the (saturation) pulse length, the approach provides a facile method for the assignment of labile protons and for the study of their exchange rate with water.

Solvent Resonance Nonexcitation

A well-established nonexcitation method is the ‘Jump-Return (JR)’ sequence. It is also known as the $[1, -1]$ method. The sequence consists of a pair of 90° hard pulses that are separated by a delay τ and have a π phase shift,

$$90^\circ_x - \tau - 90^\circ_{-x} - \text{FID} \quad [1]$$

where FID = free-induction decay. The principle of the sequence can be described using the product operator approach. The first 90°_x RF pulse generates transverse magnetization of $-I_y$. During the delay period τ , the transverse magnetization evolves at the relative frequency (ω) with respect to the transmitter

$$-I_y \xrightarrow{\omega\tau} -I_y \cos(\omega\tau) + I_x \sin(\omega\tau) \quad [2]$$

The last 90°_{-x} puts the $-I_y$ term on the right side of eqn [2] back along the z -axis of the rotating frame and the I_x term remains unaffected. The sequence thus gives rise approximately to a sineshaped excitation profile of $\sin(\omega\tau)$. The excitation bandwidth (SW_b) depends on the delay τ and is $SW_b = 1/\tau$. The maximum magnitude of the transverse magnetization can be obtained at the relative frequencies of $1/4\tau$ and $-1/4\tau$, respectively, and the two excitation bands have a 180° phase shift between them. The on-resonance solvent magnetization will be put along the z -axis and remains unchanged but the signals at the relative frequencies of $\pm 1/2\tau$ will be inverted. By increasing the number of the RF pulses from two, it is possible to make the excitation bands flatter and the suppression region narrower. One of the improved versions of this pulse sequence is the $[1-3-3-1]$ approach. A disadvantage of the general method is that it is complicated by a phase roll over the spectrum and by the effects of radiation damping. However, the saturation transfer effect remains at a minimum in these methods because of the very short overall duration, typically a few milliseconds, of the pulse sequences.

One other variation of the nonexcitation approaches is the combination of selective and nonselective sub-sequences. It consists of a soft pulse of angle β and a hard pulse of angle $-\beta$. The response to the soft pulse is

limited to a narrow range around the solvent resonance, which is cancelled subsequently by the hard pulse. The sequence thus nearly provides a flat and phased excitation profile with a gap at the solvent frequency. On the other hand, the inherent asymmetry of the method makes it sensitive to hardware imperfections.

Solvent Suppression Using Pulsed Field Gradients

Because of the advances in probe technology, PFGs have been widely used in high-resolution NMR spectroscopy for coherence selection, magnetization destruction and molecular diffusion coefficient measurement. Many of the water suppression techniques and conventional pulse sequences can be, and have been, modified using PFGs to improve suppression and to increase the spectral quality. It is rare to find a newly proposed pulse sequence not including PFGs. Reviews on the usage of PFGs in water suppression and the other specific topics are available in the recent literature.

A PFG pulse applied along the magnetic field (z -axis) direction causes the transverse magnetization (coherence) to rotate with an additional phase of

$$\phi(r) = \pi \gamma \delta G(r) \quad [3]$$

where n is the coherence quantum order, γ is the gyromagnetic ratio of the spin, r is the position of the spin in the gradient direction (the z -axis in this case), and $G(r)$ and δ are the gradient strength and duration, respectively. This position-dependent dephasing can be reversed by applying a PFG pulse of the same strength [$\delta G(r)$] but in the opposite direction. The dephasing and rephasing properties of the PFG pulses can then be used for solvent resonance suppression.

A simple and efficient pulse sequence using PFGs to dephase the water resonance is the RAW (randomization approach to water suppression, **Figure 2a**) method, in which the transverse magnetization of solvent generated by a selective 90° pulse is destroyed immediately by the following strong PFG pulse. The selective pulse can be a Gaussian-shaped soft pulse to provide a narrow-band excitation and to minimize the off-resonance excitation. Other selective pulses could be used as well. The scheme of 'sel. 90° - G_z ' can be used preceding a preparation pulse in most 2D experiments for solvent suppression. To prevent the longitudinal recovery of the water resonance during the PFG pulse, the G_z pulse can be replaced by a scheme of a composite 180° pulse sandwiched by a pair of bipolar PFG pulses, $-G_z$ - 90_x° - 180_y° - 90_x° - G_z .

The WATERGATE (water suppression by gradient-tailored excitation) method has proved popular because of its high efficiency and short duration compared with

Figure 2 Water suppression pulse sequences using PFG to selectively dephase the solvent resonance, where the bar and open symbols represent 90° pulses. (a) Randomization approach to water suppression (RAW) sequence. (b) WATERGATE (the composition of the 3-9-19 pulse train and its variations are listed in **Table 1**). (c) Double WATERGATE echo method. It is recommended that different echo times ($t_1 \neq t_2$) and different gradient strengths ($G_{z1} \neq G_{z2}$) are used.

the methods using PR or selective nonexcitation. The method resembles a spin-echo sequence with a selective refocusing pulse flanked by two symmetrical gradient pulses as shown in **Figure 2b**. Transverse coherences are dephased by the first gradient and can be rephased by the second gradient, provided they experience a 180° rotation by the selective pulses or the pulse train, denoted by W. This can be a 180° hard pulse sandwiched by a pair of 90° selective pulses. More commonly, it uses a frequency-selective pulse train of 3α - τ - 9α - τ - 19α - τ - 19α - τ - 9α - τ - 3α (denoted by 3-9-19 or W3 for short), where $62\alpha = 180^\circ$ and τ is a short delay that is used to control the null-inversion points ($\pm 1/\tau$ Hz). When either kind of selective refocusing pulse is used, the spectral resonances experience a 180° rotation and will be rephased by the second gradient pulse, whilst the net flip-angle at the water resonance frequency approaches zero and thus the water signal will be dephased by both gradient pulses. When selective pulses are used, the duration of the pulse is about 10 ms if a narrower suppression bandwidth is desired. WATERGATE with a W3 pulse train normally takes less than 5 ms, and the saturation of exchangeable proton resonances is not too serious. Another advantage of using the W3 pulse train is that the

null-points can be easily modified for off-resonance water suppression. The disadvantage of using the hard pulse train is that the peak elimination region is wider than when using presaturation and thus any resonances close to the solvent peak will be suppressed. New pulse trains with a narrower noninversion region have also been introduced. The improvement is achieved by using four (W4) or five (W5) pairs of hard pulses in the pulse train instead of three pairs as in the original W3 sequence. The experimental results (Figure 3) indicate that when more element pulses are used in the pulse train, the noninversion region becomes narrower, and the spectral profile becomes wider and flatter, but this is balanced by

Figure 3 Experimental excitation profiles of the NMR pulse sequences using W3, W4 and W5 methods. The experiments were carried out at 500 MHz. The bandwidth was set nominally to 3000 Hz ($\tau = 1/3000$ s).

some sacrifice of suppression efficiency. The composition of different hard pulse trains and parameters are listed in Table 1.

The suppression efficiency may be improved by using the double gradient-echo method (Figure 2c). Although the method provides much better suppression and phase properties, the intensities of any peaks near the solvent will be reduced because the profile of suppression has a squared form.

For comparison of PFG- and PR-based suppression methods, Figure 4a and 4b show 500 MHz ^1H NMR spectra of human blood plasma measured using the pulse sequences of WATERGATE (Figure 2c) and of NOESY-PRESAT (Figure 1c) at 30°C, respectively. The low-field region was enlarged and plotted as an inset for both spectra. The experiments were carried out under identical conditions with the exception of the different pulse sequences. The pulse train of W5 was used as the refocusing pulse for the WATERGATE and the inversion bandwidth was set to 3000 Hz ($\tau = 1/3000$ s). A 2 s PR_x and a 100 ms PR_y low-power ($\gamma B_1 = 60$ Hz; where B_1 is the RF magnetic field) pulse were used for solvent saturation in NOESYPRESAT. Both methods provide a high efficiency of solvent suppression; however, the resonances of labile protons (marked by arrows) were observable in Figure 4a but suppressed in Figure 4b by the saturation transfer effects.

Solvent Suppression Using Relaxation, Diffusion or Multiple Quantum Filters

Spin and molecular properties that distinguish water from solute signals could be used for the water resonance suppression. The most frequently used properties are the longitudinal relaxation time (T_1 , also known as the spin-lattice relaxation time), the molecular diffusion coefficient (D) and double quantum or multiple quantum coherence filters.

In biological samples, the longitudinal relaxation times of spins in a protein or other large molecule are

Table 1 WATERGATE pulse sequence parameters

Pulse type	Pulse train composition (deg) ^b	Phasing for null-points ^c at k/τ	Phasing for null-points ^c at $(2k+1)/\tau$

often in the region of tens or hundreds of milliseconds, while those of solvent water are 2 to 3 s. Such a large difference in relaxation times makes it possible to suppress the water signal using an inversion recovery scheme (**Figure 5a**). A π pulse inverts the magnetization of both solvent and solutes. The remaining transverse magnetization is dephased by the PFG pulse, which also blocks the relaxation pathway associated with the radiation damping effect. The observation pulse is applied when the longitudinal magnetization of water becomes null, after a time $T_1^w \ln 2$, where T_1^w is the longitudinal relaxation time of water. The spins in larger molecules with smaller T_1 s relax much faster and get closer to their equilibrium magnitude at the time of $T_1^w \ln 2$. For small solute molecules with similar longitudinal relaxation times, the π pulse can be replaced by a selective pulse applied at the solvent resonance. Another variation is the use of a series of selective pulses with small flip angles, each of the selective pulses being followed by a PFG pulse. The major advantage of this T_1 filter method is its higher selectivity since it provides less attenuation of the resonances close to that of the solvent.

It is also possible to attenuate the water resonance in biofluids and other aqueous samples by the addition of a reagent that causes a significant reduction of the water T_2 . The broadened water peak can then be attenuated by measuring the spectrum using a spin-echo pulse sequence. This can be achieved for biofluid samples by adding substances containing exchangeable protons that cause water to exchange at an intermediate rate and induce a line broadening. Commonly, guanidinium chloride is used. Alternatively, addition of a paramagnetic ion would also be effective, although care must be taken not to broaden the solute resonances in this case.

Figure 5b shows the diffusion coefficient (D) filtering method. The method utilizes the difference in molecular mobility between water and solutes such as macromolecules. In this experiment, the signal magnitude (M) is attenuated according to

$$M = M_0 \exp[-D(\gamma\delta\Delta G_z)^2(\Delta - \delta/3)] \quad [4]$$

where Δ is the time interval between the leading edges of the two PFG pulses, and G_z and δ are the PFG pulse

Figure 5 Solvent suppression pulse sequences based on filtering methods. Method (a) uses a T_1 filter to discriminate resonances of solvent and solutes. The difference in molecular diffusion coefficients is used in method (b). T_e is the spin-echo time. (c) Double-quantum filtering COSY, which uses the fact that there is no J -coupling between the two equivalent protons in water molecules and thus it cannot be excited to higher quantum coherence. The PFG pulses in (a) and (b) are used to attenuate radiation damping effects and dephase any transverse magnetization. They are used for the desired coherence selection in (c).

strength and duration, respectively. The diffusion coefficient of water is more than 10 times that of most larger biological molecules, and thus the water signal will be attenuated, resulting in a spectrum of larger or less mobile molecules. Since D is a molecular property, the attenuation to different spins in a molecule will be the same. This should be useful for quantitative measurement. The diffusion filtering method has now been implemented into most conventional 2D pulse sequences used for diffusion coefficient measurement and for the editing of complex NMR spectra.

The multiple-quantum filtering (MQF) method is an efficient approach to suppression of any resonance that does not experience a specific defined quantum order during the pulse sequence. Since water protons give rise to a single peak in an NMR spectrum and cannot be excited to a quantum order higher than unity, the water resonance cannot pass an MQF and will be eliminated from the spectrum. However, when the MQF is built up based on ^1H – ^1H spin coupling, the resulting spectrum is expected to have a dispersive line shape on the coupling splittings, and thus the homonuclear MQF is commonly used for 2D NMR experiments. For example, the pulse

sequence of double quantum filtered (DQF) COSY is shown in **Figure 5c**, in which PFG pulses are used to enhance the selectivity. A heteronuclear MQF NMR spectrum often has in-phase line shape, but generally the lower natural abundance of heteronuclei will reduce the sensitivity.

Postacquisition Data Processing

As discussed in previous sections, a variety of solvent suppression methods are available. However, even when a high-quality method is used, it is quite common for there to be phase or baseline distortion (or both) in the resulting spectrum, especially in the region of the solvent resonance. In other cases, although the water peak is suppressed, it still remains as the largest peak in the spectrum. This will cause serious ridges (known as ' t_1 noise') in the F_1 dimension of multidimensional NMR experiments and will strongly affect the cross peaks close to it. These disadvantages can be overcome by postacquisition data processing. It has been a standard approach to eliminate a (solvent) signal using a frequency filtering method on most modern NMR spectrometers. Some NMR machine manufacturers also provide software packages of linear prediction and maximum entropy to enhance the quality of NMR spectra and to extract more information from the spectra. However, most off-line data processing methods are focused on automatic baseline correction and convolution, and filtration or subtraction of solvent signal from time- or frequency-domain data sets. The water signal is commonly considered as being a Lorentzian line shape. In some cases it can be treated as a Gaussian function or a weighted Lorentzian–Gaussian function, and can be subtracted from the spectrum or, more commonly, from the time-domain data.

Radiation Damping Effects on Water Suppression

When water is used as solvent in ^1H NMR spectroscopy, radiation damping is not avoidable, but its effects can be minimized if a proper solvent suppression method is applied. So far radiation damping has been regarded as a negative effect on ^1H NMR experiments when water is used as the solvent, although some positive use of radiation damping has been proposed. Radiation damping is a dynamic process similar to the longitudinal relaxation, both leading the magnetization towards the equilibrium state. Physically, radiation damping is caused by the interaction of the FID current with the magnetization itself, and is characterized by a time constant T_{rd} , defined by $2(\mu_0\gamma\eta Q M_0)^{-1}$, where μ_0 is the vacuum permeability, η is the filling factor of the sample in the probe, Q is the

quality factor of the detection coil. The large values of η and Q of the probe and huge magnetization of water make the radiation damping time very short (in the region of milliseconds), much shorter than its true relaxation time T_1 at low concentration (in the region of seconds). As a result, radiation damping interferes with water suppression in many ways.

Among the four experimental strategies discussed above, some could be seriously affected by radiation damping, while others may not be. Because the RF irradiation tends to null the total magnetization, radiation-damping effects will be correspondingly removed. It has been shown that during continuous-wave irradiation, the decay of the magnetization is dependent on T_1 , T_2 and the inhomogeneous contributions from both the static field B_0 and the RF field B_1 , but is independent of radiation damping. The PR method has proven to be a reliable method for water suppression, but with the disadvantage of saturation transfer for exchanging systems. As for the PFG method, if only z -gradients are used, radiation damping could occur. Since z -gradients can destroy the transverse magnetization only, the remaining longitudinal magnetization, if it is in the $-z$ direction and is still very strong, can easily evolve into a transverse magnetization under the influence of a radiation damping field. As a result, there will be a strong water signal in the spectrum. Care should also be taken when the refocusing PFG is used, since after the refocusing, the transverse magnetization will behave as if PFG were not applied. It should be pointed out that only the positive longitudinal magnetization does not lead to radiation damping. Thus, in order to prevent radiation damping from occurring, PFG experiments should be carefully designed.

If neither PR nor PFG is used, radiation damping may bring about serious problems in water suppression. Because the water magnetization is not attenuated by hard pulses, radiation damping would make the $[1, -1]$ sequence, the inversion-recovery sequence and the DQF-COSY sequence useless, as far as water suppression is concerned. For the simple inversion-recovery method for example, after the spin inversion, the water magnetization returns to the z -direction more quickly than the spins in large molecules because of the short radiation damping time. Therefore, it is not possible to use the simple inversion-recovery sequence to measure the relaxation times, nor as a relaxation filter, unless PFG is utilized. In fact, the $[1, -1]$ method, the inversion-recovery method and MQF method have been improved significantly by PFG modifications.

Summary

Solvent suppression has been one of the rich areas in biological NMR research. The driving force comes from

in vivo and *in vitro* proton NMR spectroscopy, protein structure determination, metabolic and toxicological studies of biofluids, and medical and functional magnetic resonance imaging. New methods could emerge from the following two fundamental techniques:

1. development of fast switching B_0 and B_1 gradient coils. A high-quality gradient facility is essential for all types of NMR experiment, including solvent suppression. The use of switching gradients means that transverse magnetization is rapidly dephased, and less signal attenuation caused by diffusion and magnetization transfer results. A properly self-shielded gradient coil can minimize the eddy-current effect which can cause phase distortion throughout the spectrum. The use of magic angle PFGs has proved to be very efficient in the suppression of the solvent resonance and for reducing artefacts in 2D experiments.
2. development of precise and flexible phase- and amplitude-controlled excitation pulses. This facilitates the design of pulse sequences that could produce an exact excitation profile for the solvent peak. Since HPLC-NMR has become more and more routine, the development of double and multiple solvent-peak suppression methods will become important.

Whatever the fundamental technique a new method is based on, it should provide excellent baseline and phase properties and high suppression efficiency, have a short duration to avoid suppression transfer and be easy to be implemented into 1D and n D pulse sequences.

$\nu(\omega/2\pi)$	characteristic frequency
ρ	phonon spectral density
ω	frequency
Ω	cut-off frequency

Conventionally, nuclear magnetic resonance (NMR) spectroscopy may be viewed as proceeding by photon-stimulated transitions between energy levels of certain nuclei that are quantized due to the influence of a strong homogeneous polarizing magnetic field. However, the required quanta ($h\nu$) of energy necessary to induce transitions need not be restricted in origin to electromagnetic radiation, but may be derived from the phonon, which is the acoustic analogue of the photon. An acoustic wave, which is manifest as sinusoidal pressure variations with a characteristic frequency ν ($\omega/2\pi$), can be considered to be composed of a beam of phonons each carrying energy quanta of $h\nu$. The pressure wave and phonon approaches may be invoked to explain various acoustic phenomena. For example, phonons can be considered to be capable of facilitating both experimentally stimulated and naturally occurring nuclear relaxation transitions in solids. On the other hand, the wave approach proves convenient for describing nuclear relaxation processes, and also cavitation, in liquids. Ultrasound can be used experimentally to stimulate NMR transitions, modify nuclear relaxation processes, narrow the resonance bands derived from solids and modify the spectra of solutes dissolved in liquid crystals.

Principles

Phonons and Nuclear Spin-Lattice Relaxation

Before considering the various possibilities of experimentally manipulating nuclear spin systems with sound

it is beneficial to summarize the role of phonons in naturally occurring nuclear relaxation processes.

Debye's theory of the specific heats of solids depends on the existence of a high number of standing, high frequency, elastic waves that are associated with thermal lattice vibrations. Central to his approach is the proposal that in a solid the phonon spectral density (ρ) increases continuously, and with a direct dependence on the square of the frequency (ω) to a cutoff frequency (Ω , at about 10^{13} Hz) above which the phonon density vanishes: for a solid continuum containing N atoms in a sample of volume V , the proportionality constant is $6V/v^3$, where v is the velocity of propagation. At a typical nuclear Larmor frequency (ν_0) of around 10^9 Hz there will be a significant phonon spectral density that could facilitate nuclear spin-lattice relaxation. It emerges that the transition probability for such a direct process is very low. However, phonons at frequencies other than ν_0 can contribute to relaxation through indirect processes. Of those possible, one can involve two phonons that could be involved sequentially in absorption or emission, but the probability of this happening is extremely low simply because the number of pairs of phonons having energies that combine to match the required transition energy is very low. An alternative indirect process is the so-called Raman process in which a phonon of frequency ν interacts with the nuclear spins to cause either absorption or emission with the accompanying emergent phonons having frequencies of $\nu - \nu_0$ and $\nu + \nu_0$, respectively. As absorption can only occur when ν lies between ν_0 and Ω this process is very much less efficient than emission for which ν can have any value up to Ω : despite other processes being capable, in principle, of affecting relaxation, the indirect Raman emission process can, therefore, be viewed as being responsible for spin-lattice relaxation in solid samples.

In the case of liquid lattices, the difficulty in adequately characterizing their structures renders them unsuitable for treatment by quantum mechanics. Accordingly, liquid lattices are often treated classically by considering the effects of molecular rotations and translations, with characteristic correlation times, τ , on time-dependent magnetic and electric fields that may influence relaxation processes. Accordingly, it becomes convenient to depart from the phonon description of

sound and adopt a classical view of this as the sinusoidal propagation of a pressure wave through a medium.

Ultrasound

Sound having frequencies above about 18 kHz is traditionally called ultrasound, and in addition to its frequency is characterized by its intensity and velocity of propagation through a medium. As a matter of convenience ultrasound is usually categorized as diagnostic ultrasound (as used for imaging, with frequencies in the megahertz region) or power ultrasound (as used for cleaning, welding etc., with frequencies in the kilohertz range).

The passage of ultrasound through liquids can result in some spectacular phenomena, particularly those resulting from acoustic cavitation. Simplistically, when an acoustic wave passes through a liquid it produces compression and rarefaction of the liquid on successive cycles. On the rarefaction cycle the liquid experiences reduced pressure and, provided a suitable nucleation centre is available, a small cavity will form in the liquid. As migration of entrapped vapour into the cavity depends on the surface area of the interface of the cavity with the liquid this is greater on the rarefaction (expansion) cycle and so the cavity will grow on successive rarefaction cycles. The cavity will either become stable or, over a few acoustic cycles, unstable. In the latter case, the cavity collapses catastrophically with the generation of extreme local temperatures and pressures and the emission of shock waves. If this process occurs near a solid surface, so that there is an imbalance in the force field, a microjet of liquid, starting from the region of the cavity that is most remote from the solid surface, is ejected along the internal symmetry axis of the cavity and strikes the solid surface at velocities in the order of hundreds of m s^{-1} . Evidently, ultrasound can be used below the cavitation threshold to pressure modulate the molecular motion in liquids or above the cavitation threshold to subject both liquids and solids to shock waves, liquids to extreme local temperatures and pressures, and solids to the violent impact of microjets.

Experimentation

Although ultrasound can be generated in a variety of ways, it often proves most convenient to derive it from piezoelectric transducers by applying alternating voltages across opposite silvered faces of discs of the piezoelectric materials (for example, lead zirconium titanate) that have been suitably cut to generate either longitudinal or transverse waves from their surfaces. An alternating signal, applied at the natural resonance frequency of the piezoelectric crystal, causes the surfaces of the crystal to expand and contract at the resonance frequency so that

corresponding sinusoidally varying pressure waves are generated and propagated in the desired direction through chosen media.

For many NMR purposes, acoustic waves are often transmitted to liquids using metal (such as titanium) horns that are coupled to one of the piezoelectric crystal faces, or more simply by enabling intimate contact between the crystal and the liquid: to provide acoustic transmission through solids the transducer can be bonded directly to an optically flat surface of the solid.

In the first low frequency (20 kHz) ultrasound/NMR experiments, the ultrasound was delivered to samples in a conventional iron magnet NMR spectrometer using apparatus similar to that shown in **Figure 1**. The titanium alloy horn used was sufficiently long (77 cm) to enable the piezoelectric device to be remote from the NMR detector region as the latter is sensitive to pick-up of extraneous a.c. signals. The horn was machined to provide exponential reduction in its diameter both to provide a coupling tip capable of fitting inside a conventional NMR tube and also to provide mechanical amplification of the ultrasound. Evidently, this equipment with its physically large horn is not suited to insertion down the bore of cryomagnets. Consequently, devices have been produced that are particularly suited to operation with MHz ultrasound and which can be easily inserted into the top of NMR sample tubes in cryomagnets: such a device is illustrated schematically in **Figure 2**. Essentially, this facilitates electrical contact

Figure 1 Early 20 kHz SINMR apparatus.

Figure 2 Schematic diagram of a transducer assembly capable of generating high intensity ultrasound in the megahertz region. Reproduced with permission from RL Weekes, Ph.D. thesis, Aston University, 1998.

with the piezoelectric transducer by way of compressional contacts and enables the latter to be brought into intimate contact with liquid samples about 1 cm above the active NMR coil region where little pick-up by the latter from the former is experienced: now, similar devices to that shown in **Figure 2** have been constructed that allow acoustic irradiation of NMR samples from underneath. By using this general approach NMR/ultrasound experiments have become possible at acoustic frequencies up to 10 MHz. It is worth noting that many high frequency piezoelectric transducer discs have an impedance that can be matched to the output of readily available, and relatively inexpensive, transceiver devices that can, therefore, be used to drive the transducers without extensive modification.

Naturally, when contemplating high acoustic frequency/NMR experiments in cryomagnets it was a matter of priority to resolve two questions. First, does the introduction of ultrasound into the bore of a cryomagnet cause the latter to quench? Extensive experiments have shown that even with acoustic intensities approaching 500 W cm^{-2} the magnets do not quench, although

naturally caution is recommended when undertaking such experiments. Second, what is the limit of acoustic frequency at which cavitation can be induced? Using the self-indicating colour-sensitive Weissler reaction as dosimeter it has been shown that cavitation can readily be achieved at frequencies up to 10 MHz, without the involvement of undertones of the transducer natural frequency.

Applications

By extrapolation of the role of lattice phonons in nuclear relaxation processes in solids it is not a great step to appreciate that the application of ultrasound to both solids and liquids may be used to manipulate phenomena of interest to NMR spectroscopists. Although not yet an area of considerable activity the relatively few examples of the combined use of NMR and ultrasound that will now be described indicate that further such studies will prove profitable.

Acoustic Nuclear Magnetic Resonance (ANMR)

If a solid is irradiated with ultrasound, it produces a phonon spectral density that is much larger than the spectral density arising from natural lattice vibrations at the irradiation frequency. If acoustic irradiation is at the Larmor frequency of dipolar nuclei, the rate of stimulated transitions is increased by a factor of about 10^{11} , but this is probably insufficient to make the detection of acoustically stimulated transitions detectable. However, for quadrupolar nuclei the ultrasonic transition rates can be increased by a further factor of about 10^4 and enable the observation of net acoustic energy by ANMR despite the competition from relaxation transitions. The selection rules for allowed transitions due to quadrupolar coupling are $\Delta m = \pm 1$ (but not $m = -\frac{1}{2} \leftrightarrow +\frac{1}{2}$) and ± 2 . Accordingly, ANMR (which is not susceptible to skin depth problems) can be detected at both ν_0 and $2\nu_0$. Although ANMR can, with difficulty, be detected directly, it is usual to detect its effect through the additional saturation of NMR signals that are detected normally through stimulation by RF irradiation.

Although there are many examples of ANMR experiments on solid samples, there has been considerable debate as to whether similar experiments are possible using liquid samples. This debate appears to have been resolved by relatively recent work on ^{14}N ($\nu_0 = 6.42 \text{ MHz}$ at a magnetic field of 2.1 T) ANMR saturation experiments on acetonitrile and *N,N*-dimethylformamide using acoustic frequencies ranging from about 1 MHz to 10 MHz. Only at an acoustic frequency corresponding to the nuclear Larmor frequency was saturation of the ^{14}N signal observed, using an acoustic intensity of about 2.5 W cm^{-2} .

Acoustically Induced Nuclear Relaxation

If solids are irradiated with ultrasound having a frequency below the nuclear Larmor frequency, reference to the discussion of the Raman phonon relaxation process indicates that relaxation emission transitions should be favoured and that spin-lattice relaxation times might be reduced. Correspondingly, the acoustic modulation of normal molecular motion in liquids might result in the reduction of T_1 . The earliest indication that T_1 can be reduced by the application of ultrasound derived from work on an aqueous colloidal sol of As_2S_3 when, in the 1960s, a reduction in T_1 was noted. Since that observation, detailed investigations have been undertaken on the effects of ultrasound, at various frequencies and intensities, on the values of T_1 for 1H , ^{13}C and ^{14}N in several liquids and liquid mixtures. Importantly, it has been established that the normal values of T_1 in liquids can be reduced by irradiation with ultrasound. Although the acoustic frequency used (1–6 MHz) appeared to have little effect on the observations, it was found that as the acoustic intensity was increased the value of T_1 decreased by up to 60% of its natural value, and that the extent of the decrease appeared to correlate roughly with the molecular environment of the nucleus studied. As, for the small molecules studied, the nuclei were all in their extreme narrowing limit (short correlation times) a possible explanation for the reduction in the values of T_1 is that their correlation times were increased by the application of ultrasound. This is not inconsistent with the rarefaction–compression effects of the acoustic pressure wave, which may be considered to impose on the molecules a motion that corresponds to a dominant translational correlation time of the order of the inverse of the acoustic frequency ($\sim 10^{-6}$ s). It was also observed that as the intensity of the ultrasound was increased further the values of T_1 increased from the minimum value achieved. Although several explanations of this increase in T_1 are possible, it is most likely that it arose as a result of the rather crude apparatus used, causing heating of the samples and a normal increase in T_1 . Recently, further investigations of the acoustic reduction in the values of T_1 have been conducted using improved apparatus. The now reproducible results show that T_1 for liquid samples can indeed be progressively reduced, to a limiting value, by the systematic increase in intensity of the acoustic field. **Figure 3** shows typical plots of the signal-to-noise ratio of the ^{13}C quaternary carbon of 1,3,5-trimethylbenzene in cyclohexane with increasing acoustic intensity at 2 MHz and reflects the progressive reduction of T_1 . If the explanation for the reduction in the values of T_1 for nuclei in the liquid phase is in fact that the ultrasound imposes a dominant translational correlation time on small molecules, an exciting possibility, is that the choice of a suitable acoustic frequency could be used

Figure 3 Dependence on 2 MHz ultrasound intensity of the ^{13}C signal-to-noise ratio for the quaternary carbon of 1,3,5-trimethylbenzene in a 1:1 molar mixture with cyclohexane. Reproduced with permission from AL Weekes, Ph.D. thesis, University of Aston, 1998.

to modify the correlation times of large biomolecules and hence reduce the associated values of T_1 and speed up their study by NMR. Such an approach, however, has accompanying problems, not least of which is the possibility that the application of ultrasound may cause conformational changes to the macromolecules studied. Similar changes have been observed during studies of *N,N*-dimethylacetamide where increasing intensity of 20 kHz ultrasound was found to induce free rotation about the $N-C=O$ single bond and cause averaging of the two *N*-methyl 1H chemical shifts to a single value.

It has also been demonstrated by other workers that ultrasound can reduce T_1 for a gadolinium chloride solution, and they, like the originators of the technique, have suggested that the approach might find use in magnetic resonance imaging: this exciting possibility remains to be investigated.

Although less work has been done on the acoustic reduction of T_1 in solids than in liquids, it has been established that, as for liquids, the natural values of T_1 in solids can be reduced by the application of ultrasound. By coupling 20 kHz ultrasound to a sample of trisodium phosphate dodecahydrate in an open mesh nylon sack immersed in a liquid, the normal value of the ^{31}P T_1 was reduced from 7.1 s (obtained from MAS NMR measurements) to 2.1 s. Subsequently, similar reductions (by a factor of about two) have been observed for the values of T_1 for ^{13}C in diamonds to which high frequency piezoelectric transducers were bonded directly.

Ultrasound and the NMR of Liquid Crystals

Due to the anisotropy in the molecular magnetic and electrical properties of liquid crystals they can, when in their nematic mesophase, be orientated by the application of external magnetic and electric fields. In the context of NMR this enables liquid crystals containing low concentrations of dissolved solutes to be orientated

by the magnet polarizing field. One beneficial consequence of this is that the solutes themselves become orientated and yield NMR spectra which show dipolar spin coupling splittings and which are quite different from their usual isotropic liquid state spectra. These, for example, enable the solute molecules structures to be determined. If a liquid crystal, in its nematic mesophase, is located in a magnetic field alone, the molecular director adopts a reasonably well-defined orientation with respect to the direction of the applied field. If, in a constant magnetic field, the orientation of the liquid crystal director can be changed, the appearance of the spectra of dissolved solutes should be changed. The possibility of using ultrasound to manipulate the director orientation of both thermotropic and lyotropic liquid crystals in appropriate NMR magnets has been investigated. The ^2H spectrum of benzene- d_6 dissolved in the nematic liquid crystal ZLI-1167, which normally aligns with its director perpendicular to the direction of the applied magnetic field, was studied at about 30°C below the clearing temperature, both with and without the application of ultrasound along the bore of a cryomagnet. In the absence of ultrasound, the normal ^2H spectrum, composed of a pair of sharp quadrupolar split resonances, was observed. When the sample was irradiated with 2 MHz ultrasound the ^2H resonances broadened as shown in **Figure 4**. A temperature gradient within the sample should result in tails between the inner edges of the two resonances the minimum separation between

which corresponds to the sample being close to the clearing temperature. On the other hand, a gradient in the director orientation should result in outer trailing edges to the resonances, as observed. Analyses of several such spectra led to the conclusion that the ultrasound, possibly through acoustic streaming, can result in a dispersion of the normal director orientation with a maximum induced change of about 20° from the normal direction.

SINNMR Spectroscopy

It is well known that the width of the naturally broad resonances arising from static solids can be reduced by the coherent averaging processes that result from rapidly spinning samples about so-called magic angles. For dipolar nuclei the magic angle is set at $54^\circ 44'$ in the MAS NMR technique, while for quadrupolar nuclei an additional magic angle is used in the double orientation rotor, or DOR, method in order to minimize second order quadrupolar broadening effects. This is not necessary for liquids where the normally rapid and random molecular motion leads naturally to narrow lines with isotropic characteristics. Evidently, if particulate matter could be made to mimic the motional characteristics of (large) molecules in the liquid phase, and undergo rapid random motion, it should be possible to narrow the resonances from the solids through an incoherent motional process. If this situation could be achieved without

Figure 4 ^2H NMR spectrum of benzene- d_6 in liquid crystal ZLI-1167 irradiated with 2 MHz ultrasound at $\sim 20\text{ W cm}^{-2}$. Reproduced with permission from SA Reynolds, Ph.D. thesis, Aston University, 1997.

spinning the sample, the production of spinning sidebands, which confuse MAS NMR and DOR spectra, could be avoided.

There are several possible ways of inducing the necessary incoherent motion of particles to facilitate their resonance line narrowing. An obvious way is to produce a fluidized bed in the NMR sample tube, but this has been tried without success. An alternative is to utilize the effects of Brownian motion where molecular bombardment of fine particles in suspension can cause their incoherent motion. The latter approach (ultrafine particle NMR) has been demonstrated using very small particles (nm size) that were perceived to be necessary to respond appropriately to Brownian motion. The necessity to use extremely small particles for this type of experiment is open to question because many experiments in the author's laboratory have shown that micrometre-sized particles, suspended in density matched liquids, respond to Brownian motion and yield resonances that are significantly reduced relative to those from static solids.

Another way of inducing appropriate incoherent motion of suspended particles, and producing narrow resonances from solids, is to irradiate the suspension with ultrasound. Whilst this idea relies on the consequences of several phenomena such as streaming, cavitation and shock waves, it may be considered initially from the viewpoint of early theoretical treatments of a single particle subject to an acoustic field. These showed that, for a physically anisotropic particle, the application of an acoustic field will drive the particle to one of three equilibrium orientations of which that with the long particle axis parallel to the direction of the acoustic field is the most stable. Having achieved the most stable equilibrium configuration any motional perturbation from this will be followed by a very rapid return to the equilibrium orientation, i.e. the particle will rotate rapidly through some relatively small angle in a more or less coherent fashion. Obviously this is not what is required to narrow the resonance lines arising from the solid. However, when an assembly of many particles is subject to acoustic irradiation the effects of cavitation producing microjet impact on particles will cause them to rotate, as will shock waves. The sequential effects of these phenomena, together with the effects of induced interparticle collisions, can be adequate to cause rapid incoherent rotation of the particles. These principles are implicit in the sonically induced narrowing of the NMR spectra of solids (SINNMR) technique that was first demonstrated in 1991.

There are so many interdependent parameters (such as support liquid density and viscosity, particle size, and acoustic frequency and intensity) that govern the success of the SINNMR experiment that it can by no means yet be considered a routine analytical tool. Nevertheless, continuing extensive investigations are slowly revealing

the key features of the experiment and some of the findings are worthy of particular note.

The technique was placed on a fairly reproducible basis, using 20 kHz ultrasound delivered via a long titanium alloy acoustic horn to suspensions contained in a normal NMR high resolution tube in an iron magnet-based spectrometer. Work on resin-coated (to prevent chemical reaction) 'particles' of aluminium and its alloys resulted in the production of ^{27}Al SINNMR spectra which revealed resonances of full width at half maximum height (FWHM) as low as 350 Hz: this compares most favourably with the FWHM of about 700 Hz obtained using MAS NMR and the FWHM of about 9000 Hz for a static sample of aluminium. The fact that the SINNMR resonances showed Knight shifts typical of the metallic species appears to provide an unequivocal proof of the validity of the SINNMR experiment. Subsequent studies of the ^{23}Na and ^{31}P spectra of trisodium phosphate dodecahydrate provided valuable insight into the SINNMR experiment. ^{31}P measurements of relaxation times using both MAS NMR and SINNMR revealed that the acoustically induced particle correlation times are of the order of 10^{-7} s, which is quite fast enough to cause the motional narrowing of the NMR spectra of the suspended solids. Interestingly, it was shown that the correlation times of the particles reduced as their size increased in support media of decreasing density and viscosity. Somewhat disappointingly, however, these detailed studies revealed that under the conditions employed only about 2% of the solid sample participated in the SINNMR narrowing. Such a low efficiency of SINNMR would appear to render it a poor competitor to MAS NMR and DOR. Nevertheless, the potential value of SINNMR has been established through successful narrowing of ^{11}B , ^{27}Al , ^{29}Si , and ^{23}Na resonances in a range of materials, including glasses. In view of this a concerted thrust has been initiated to both improve the sensitivity of the technique and reduce its complexity.

The most recent work on SINNMR has resulted in the development of the first dedicated acoustic/NMR probehead. This accepts special SINNMR sample tubes that contain a piezoelectric transducer (interchangeable so that a range of acoustic frequencies from 1 to 10 MHz can be used) at its base. This configuration permits the ultrasonic irradiation of particles in less dense support liquids so that the particles can be levitated by the acoustic field and induced to undergo incoherent motion in the NMR coil region. The use of ultrasound in the MHz range should produce smaller cavities and facilitate the study of much smaller particles than those used in the 20 kHz experiments, because the latter generates cavities of about 90 μm and microjetting from these is only effective with particles whose size is greater than the cavity dimensions. The reproducibility and efficiency of the SINNMR experiment has been improved using this

Figure 5 The ^{23}Na NMR spectra of particulate trisodium phosphate dodecahydrate suspended in a bromoform/chloroform mixture (a) without acoustic irradiation and (b) and (c) irradiated with 2 MHz ultrasound at ~ 30 and 50 W cm^{-2} respectively. dedicated apparatus and the preliminary results are most encouraging: typical SINNMR spectra are shown in **Figure 5**. When designing the dedicated SINNMR probehead and vessel mentioned above, particular attention was devoted to avoiding significant heating of the sample. As a result of this the apparatus can be used, not only for SINNMR studies, but for the reduction in the values of T_1 for liquid samples. This is now routinely possible for small molecules and the possibility of inducing similar changes in macromolecules is now the

subject of investigation. However, the implementation of sonically-induced NMR has not progressed significantly in the past few years but it remains nevertheless an intriguing approach.

Introduction

The SPECT technique is part of the armoury of nuclear medicine for the diagnosis of pathological conditions. Unlike other imaging techniques such as X-ray tomography or even some uses of magnetic resonance imaging (MRI), this technique can be used to identify functional abnormalities rather than anatomical disturbances. This article provides a brief overview of the general principles and operation of the technique and detailed explanations are given in other articles in this encyclopedia, as listed in the See also list.

SPECT involves the injection into the body of a radioactive pharmaceutical product (a radionuclide) such as technetium-99m or thallium-201 which decays with the emission of gamma rays. Usually the radiopharmaceutical is a protein with the radioactive atom attached and the molecule is designed to have the desired absorption properties for the tissue to be imaged. Some are accumulated into heart muscle and are used for cardiac imaging, whilst others penetrate the brain and are used for studying brain function. Yet others can be targeted to the lungs. Thus a healthy tissue will take up a known amount of the SPECT agent and this then appears as a bright area in a SPECT image. If a tissue is abnormal, it is possible that uptake of the radiopharmaceutical will be amplified or depressed according to circumstances and then this will appear as a more intense spot or a dark area, respectively, on the image. This can be interpreted by a nuclear medicine expert in terms of the suspected pathological state.
